About the Author and Whatis.com

This book is based on a Web site, whatis.com, created by Lowell Thing in September, 1996, as an experiment in hypertext and also as a place for some information he was always forgetting. The original idea was to see how many useful hypertext links could fit on a Web page, and he wrote the first few topics in order to see what the idea would look like. One topic led to another and, by mid-2001, Lowell and some freelance contributors had written 3,500 definitions.

In February 2000, Whatis.com was purchased by TechTarget, a diversified media company providing targeted IT media to technology professionals. Lowell continues to play an active role as Editor of the site. Whatis.com currently serves more than one million visitors each month.

Lowell lives in Kingston, New York, with his wife, Suzanne. Their daughter, Emily, created the logo that was used during whatis.com's first three years, and their daughter, Hillary, contributed some of the first definitions. Lowell was formerly a technical writer and information planner for IBM. He is a senior member of the Society for Technical Communication.

Credits

TechTarget Co-Founders: Greg Strakosch and Don Hawk

Editor-in-Chief, TechTarget: Paul Gillin

Editor, whatis.com: Lowell Thing

Assistant Editor: Margaret Rouse

Cover Copy: Lisa Johnson

Cover Design: Frank Remick

Project Coordinator: Ed Montes

Senior Contributing Writers: Stan Gibilisco, Ivy Wigmore, and Sherri Wilson

Other Contributors: Megan Brady, Sean Brooks, Teresa Buday, Christine Campbell, Gordon Carrolton, Joyce Chutchian, Marilyn Cohodas, William W. Collier, Jim Connolly, Patricia Ellis, Crystal Ferraro, Sean Ford, David Gabel, Cathy Gagne, Kara Gattine, Joda Glossner, Karen Guglielmo, Paul Healey, Michele Hope, Jennifer Hubley, Laura Hunt, Joann Ives, Steve Jacobs, Dick Kennedy, Catherine Ketcher, Mark Lewis, Heather McCarthy, Fred McIntyre, Mary Michaud, Joseph Oliver, Jon Panker, Eric Parizo, Borys Pawliw, BJ Rama, Matt Savage, RJ Schille, Jeremy Selwyn, Jim Shaughessy, Stephen Simpson, Simon Smith, David Spenard, Sean Tierney, Steven Vagle, and many others.

Acknowledgements

I'd like to thank Deborah Kaufman, Greg Correll, and Joseph Flanigan for being the first great fans of whatis.com and for helping to build a Web site that became something of an institution. I also seize this opportunity to hug and kiss my wife, Suzanne, in print for her absolute support, love, and good humor without which even the first 10 definitions would never have been written.

I would also like to thank Jim Connolly for being the first to see how whatis.com could fit into TechTarget; Ken Berquist and Bob Taylor for making it happen; Paul Gillin, Editor-in-Chief, for his overall guidance; and Don Hawk and Greg Strakosch for folding whatis.com into their own great idea while extending its possibilities. I would also like to thank Margaret "Peggy" Rouse for demanding that I hire her and for making our jobs so much fun.

Finally, I would like to thank the thousands of people worldwide who contributed to whatis.com during the first five years of its existence. In the first days, it was users from such places as Riga, Nairobi, and Ulan Bator who made the Web such an exciting place to be and who spurred us on with their thanks and suggestions. Turning whatis.com into a book seems like the end of Phase One. I invite the users of this book and the Web site to help us build Phase Two of what we like to hope will become the world's greatest mental construct about information technology.

Lowell Thing

How to Use This Book

You can look up any term by the alphabetical listing.

You can test your knowledge of IT vocabulary by picking out a term and seeing if our definition matches yours.

You may also be able to find the information you need in our "Fast References" section (for example, DSL, transmission speeds, prefix multipliers, fundamental physical units, and so forth).

For a term so new that it may not be in this book, visit the whatis.com Web site. We may have it and, if we don't, you can suggest that we add it.

For a given term, you may also want to visit whatis.com to see the Web sites we recommend for more information about the term.

Some notes about our definitions:

We report which terms are being used in information technology and what they currently mean. We report usage, and, only when it seems helpful, do we recommend a preference.

Because information technology changes rapidly, a definition can become outdated. If in doubt, the best source is always an authority such as the IEEE, the IETF, and similar standards or technology-sponsoring organizations.

We try to describe a term uniquely in the first sentence or two as you would in a dictionary. The rest of the definition is an elaboration that describes the term as you would in an encyclopedia.

We describe pronunciation only for terms we think some users will want to know how to pronounce.

FAST REFERENCES

Chat Abbreviations

Chat abbreviations are commonly used in e-mail, online chatting, instant messaging, and conference postings.

Abbreviation	Meaning
ADN	Any day now
AFIK	As far as I know
AFK	Away from keyboard
ARE	Acronym-rich environment
A/S/L?	Age/sex/location?
B4N	Bye for now
BAK	Back at the keyboard
BBIAB	Be back in a bit
BBL	Be back later
BEG	Big evil grin
BFD	Big f***ing deal
BFN	Bye for now
BG	Big grin
BIOYIOP	Blow it out your I/O port
BL	Belly laughing
BOTEC	Back-of-the-envelope calculation
BRB	Be right back
BTA	But then again...
BTW	By the way
BWTHDIK	But what the heck do I know...?
CU	See you
CUL	See you later
CUL8ER	See you later
CYA	Cover your ass
CYO	See you online
DBA	Doing business as
DFLA	Disenhanced four-letter acronym (that is, a TLA)
DL	Dead link
DIKU	Do I know you?
DITYID	Did I tell you I'm distressed?
DQMOT	Don't quote me on this
EG	Evil grin
EMFBI	Excuse me for butting in
EOM	End of message
EOT	End of thread (meaning: end of discussion)
ETLA	Extended three-letter acronym (that is, an FLA)
F2F	Face to face
FAQ	Frequently-ask question(s)
FISH	First in, still here
FLA	Four-letter acronym
FMTYEWTK	Far more than you ever wanted to know
FOMCL	Falling off my chair laughing
FUBAR	F***ed up beyond all repair or recognition
FUD	Fear, Uncertainty, and Doubt
FWIW	For what it's worth

Abbreviation	Meaning
FYI	For your information
G	Grin
GA	Go ahead
GAL	Get a life
GD&R	Grinning, ducking, and running
GIWIST	Gee, I wish I'd said that
GMTA	Great minds think alike
GOL	Giggling out loud
GTRM	Going to read mail
HTH	Hope this helps
IAC	In any case
IANAL	I am not a lawyer (but)
IC	I see
IHA	I hate acronyms
IIRC	If I recall/remember/recollect correctly
ILU or ILY	I love you
IM	Immediate message
IMHO	In my humble opinion
IMing	Chatting with someone online usually while doing other things such as playing trivia or other interactive game
IMNHO	In my not so humble opinion
IMO	In my opinion
IOW	In other words
IPN	I'm posting naked
IRL	In real life (that is, when not chatting)
IYSWIM	If you see what I mean
JBOD	Just a bunch of disks (like redundant array of independent disks, etc.)
JIC	Just in case
JK	Just kidding
KOTC	Kiss on the cheek
KWIM?	Know what I mean?
L8R	Later
LD	Later, dude
LDR	Long-distance relationship
LLTA	Lots and lots of thunderous applause
LOL	Laughing out loud
LRF	Little Rubber Feet (the little pads on the bottom of displays and other equipment)
LTM	Laugh to myself
LTR	Long-term relationship
LULAB	Love you like a brother
LULAS	Love you like a sister
MoF	Male or female
MOSS	Member of the same sex
MOTOS	Member of the opposite sex
MUSM	Miss you so much
NFG	No f****g good
NFW	No feasible way or no f****g way
NIFOC	Naked in front of computer
NP or N/P	No problem
NRN	No response necessary
OIC	Oh, I see
OLL	Online love

Abbreviation	Meaning
OTF	Off the floor
OTOH	On the other hand
OTTOMH	Off the top of my head
PANS	Pretty awesome new stuff (as opposed to "POTS")
PCMCIA	People can't master computer industry acronyms
PDA	Public display of affection
PEBCAK	Problem exists between chair and keyboard
PIBKAC	Problem is between keyboard and chair
PITA	Pain in the ass
PMFJIB	Pardon me for jumping in but...
POOF	Goodbye (leaving the room)
POTS	Plain old telephone service
PU	That stinks!
RL	Real life (that is, when not chatting)
ROR	Raffing out roud (Engrish for "laughing out loud")
ROTFL	Rolling on the floor laughing
ROTFLMAO	Rolling on the floor laughing my a** off
ROTFLMAOWPIMP	Rolling on the floor laughing my a** off while peeing in my pants
ROTFLMBO	Rolling on the floor laughing my butt off
RPG	Role-playing games
RSN	Real soon now
RTFM	Read the f***ing manual
RYO	Roll your own (write your own program; derived from cigarettes rolled yourself with tobacco and paper)
S4L	Spam for life (what you may get when you become someone's customer or client)
SHCOON	Shoot hot coffee out of nose
SEG	S***-eating grin
SF	Surfer-friendly (low-graphics Web site)
SNAFU	Situation normal, all f***ed up
SO	Significant other
SOL	Smilling out loud or sh*t out of luck
SOMY	Sick of me yet?
STFW	Search the f*****g Web
STW	Search the Web
SWAG	Stupid wild-a** guess
TAFN	That's all for now
TANSTAAFL	There ain't no such thing as a free lunch
TFH	Thread from hell (a discussion that just won't die and is often irrelevant to the purpose of the forum or group)
TGIF	Thank God it's Friday

Abbreviation	Meaning
THX	Thanks
TIA	Thanks in advance (used if you post a question and are expecting a helpful reply)
TLA	Three-letter acronym
TLK2UL8R	Talk to you later
TMI	Too much information
TOPCA	Til our paths cross again (early Celtic chat term)
TPTB	The powers that be
TTFN	Ta-Ta for now
TTT	Thought that, too (when someone types in what you were about to type)
TTYL	Talk to you later
TU	Thank you
UAPITA	You're a pain in the ass
UW	You're welcome
VBG	Very big grin
VBSEG	Very big s***-eating grin
WDALYIC	Who died and left you in charge?
WFM	Works for me
WIBNI	Wouldn't it be nice if
WT?	What/who the ?
WTFO	What the F***! Over!
WTG	Way to go!
WTGP?	Want to go private?
WU?	What's up?
WUF?	Where are you from?
WYSIWYG	What you see is what you get
YGBSM	You gotta be s***tin' me!
YMMV	Your mileage may vary.

Emoticons (Smileys)

Emoticons (sometimes known as "smileys") are a popular form of expression on the Internet, especially in e-mail. Just type in each character one at a time to create the emoticon.

: -)	Smile
; -)	Smile with a wink
: <)	User with mustache, smiling
: -	Mad
: - (Sad
: ' - (Crying
: -	Also crying
: -)	Really happy
: - D	Big grin
: - *	A kiss
: - P~	A lick
: - o	Wow! or I'm surprised
: -	Grim

: -P	Sticking out your tongue
:-	User happens to be Popeye
:-/	Perplexed
=:0	Frightened (hair standing on end)
=80	Bug-eyed with fright
:-}	Embarrassed smile
:-)<>>>>	Basic Smiley with a necktie
;-^)	Tongue in cheek
%*@:-(Hung over
:-~~~	Drooling
>:)	Perplexed look
.)	Keeping an eye out for you
8:-)	Glasses on forehead
8:[Normal smiling face of a gorilla
0:-)	Angel
]:- [Robot
(:V)	Duck 3:-o Cow
:-]	Vampire
(_8-()	Homer Simpson
C :-=	Charlie Chaplin
= :-)=	Abe Lincoln
*<:-)	Santa Claus
-:-)	User sports a mohawk and admires Mr. T
(:)-)	Scuba diver
:-'	User has a cold
:-{}	User with heavy lipstick
:-)8	User is well dressed
>:-<	Mad
*#::-)	Scotsman wearing his Scottish tam
%-^	User is another Picasso
#-)	User partied all night
<:I	Dunce
:- "	Have an ordinary day!" Smiley
}{:	Kisses (stolen from June bug)
oooo(0) (0)oooo	Toes
(-_-)	Secret smile
#.-o "	Oh, nooooooo Mr. Bill!!!"

The Speed of...

This table shows the stated data rates for the most important end-user and backbone transmission technologies.

Technology	Speed	Physical Medium	Application
GSM mobile telephone service	9.6 to 14.4 Kbps	RF in space (wireless)	Mobile telephone for business and personal use
High-Speed Circuit-Switched Data service (HSCSD)	Up to 56 Kbps	RF in space (wireless)	Mobile telephone for business and personal use
Regular telephone service (POTS)	Up to 56 Kbps	Twisted pair	Home and small business access
Dedicated 56Kbps on Frame Relay	56 Kbps	Various	Business e-mail with fairly large file attachments
DS0	64 Kbps	All	The base signal on a channel in the set of Digital Signal levels
General Packet Radio System (GPRS)	56 to 114 Kbps	RF in space (wireless)	Mobile telephone for business and personal use
ISDN	BRI: 64 Kbps to 128 Kbps PRI: 23 (T-1) or 30 (E1) assignable 64-Kbps channels plus control channel; up to 1.544 Mbps (T-1) or 2.048 (E1)	BRI: Twisted pair PRI: T-1 or E1 line	BRI: Faster home and small business access PRI: Medium and large enter prise access
IDSL	128 Kbps	Twisted-pair	Faster home and small business access
AppleTalk	230.4 Kbps	Twisted pair	Local area network for Apple devices; several networks can be bridged; non-Apple devices can also be connected
Enhanced Data GSM Environment (EDGE)	384 Kbps	RF in space (wireless)	Mobile telephone for business and personal use
Satellite	400 Kbps (DirecPC and others)	RF in space (wireless)	Faster home and small enter prise access
Frame relay	56 Kbps to 1.544 Mbps	Twisted-pair or coaxial cable	Large company backbone for LANs to ISP ISP to Internet infrastructure
DS1/T-1	1.544 Mbps	Twisted-pair, coaxial cable, or optical fiber	Large company to ISP ISP to Internet infrastructure
Universal Mobile Telecommunications Service (UMTS)	Up to 2 Mbps	RF in space (wireless)	Mobile telephone for business and personal use (available in 2002 or later)
E-carrier	2.048 Mbps	Twisted-pair, coaxial cable, or optical fiber	32-channel European equivalent of T-1
T-1C (DS1C)	3.152 Mbps	Twisted-pair, coaxial cable, or optical fiber	Large company to ISP ISP to Internet infrastructure
IBM Token Ring/802.5	4 Mbps (also 16 Mbps)	Twisted-pair, coaxial cable, or optical fiber	Second most commonly used local area network after Ethernet

Technology	Speed	Physical Medium	Application
DS2/T-2	6.312 Mbps	Twisted-pair, coaxial cable, or optical fiber	Large company to ISP ISP to Internet infrastructure
Digital Subscriber Line (DSL)	512 Kbps to 8 Mbps	Twisted-pair (used as a digital, broadband medium)	Home, small business, and enterprise access using existing copper lines
E-2	8.448 Mbps	Twisted-pair, coaxial cable, or optical fiber	Carries four multiplexed E-1 signals
Cable modem	512 Kbps to 52 Mbps (see "Key and explanation" below)	Coaxial cable (usually uses Ethernet); in some systems, telephone used for upstream requests	Home, business, school access
Ethernet	10 Mbps	10BASE-T (twisted-pair); 10BASE-2 or -5 (coaxial cable); 10BASE-F (optical fiber)	Most popular business local area network (LAN)
IBM Token Ring/802.5	16 Mbps (also 4 Mbps)	Twisted-pair, coaxial cable, or optical fiber	Second most commonly-used local area network after Ethernet
E-3	34.368 Mbps	Twisted-pair or optical fiber	Carries 16 E-1 signals
DS3/T-3	44.736 Mbps	Coaxial cable	ISP to Internet infrastructure Smaller links within Internet infrastructure
OC-1	51.84 Mbps	Optical fiber	ISP to Internet infrastructure Smaller links within Internet infrastructure
High-Speed Serial and Interface (HSSI)	Up to 53 Mbps	HSSI cable	Between router hardware WAN lines Short-range (50 feet) interconnection between slower LAN devices and faster WAN lines
Fast Ethernet	100 Mbps	100BASE-T (twisted pair); 100BASE-T (twisted pair); 100BASE-T (optical fiber)	Workstations with 10 Mbps Ethernet cards can plug into a Fast Ethernet LAN
Fiber Distributed-Data Interface (FDDI)	100 Mbps	Optical fiber	Large, wide-range LAN usually in a large company or a larger ISP
T-3D (DS3D)	135 Mbps	Optical fiber	ISP to Internet infrastructure Smaller links within Internet infrastructure
E-4	139.264 Mbps	Optical fiber	Carries 4 E3 channels Up to 1,920 simultaneous voice conversations
OC-3/SDH	155.52 Mbps	Optical fiber	Large company backbone Internet backbone
E-5	565.148 Mbps	Optical fiber	Carries 4 E4 channels Up to 7,680 simultaneous voice conversations

The Speed of...

Technology	Speed	Physical Medium	Application
OC-12/STM-4	622.08 Mbps	Optical fiber	Internet backbone
Gigabit Ethernet	1 Gbps	Optical fiber (and "copper" up to 100 meters)	Workstations/networks with 10/100 Mbps Ethernet plug into Gigabit Ethernet switches
OC-24	1.244 Gbps	Optical fiber	Internet backbone
SciNet	2.325 Gbps (15 OC-3 lines)	Optical fiber	Part of the vBNS backbone
OC-48/STM-16	2.488 Gbps	Optical fiber	Internet backbone
OC-192/STM-64	10 Gbps	Optical fiber	Backbone
OC-256	13.271 Gbps	Optical fiber	Backbone

Kilo, Mega, Giga, Tera, Peta, and All That

Kilo, mega, giga, tera, and peta are among the list of prefixes that are used to denote the quantity of something, such as, in computing and telecommunications, a **byte** or a **bit**. Sometimes called prefix multipliers, these prefixes are also used in electronics and physics. Each multiplier consists of a one-letter abbreviation and the prefix that it stands for.

In communications, electronics, and physics, multipliers are defined in powers of 10 from 10^{-24} to 10^{24} , proceeding in increments of three orders of magnitude (10^3 or 1,000). In IT and data storage, multipliers are defined in powers of 2 from 2^{10} to 2^{80} , proceeding in increments of ten orders of magnitude (2^{10} or 1,024). These multipliers are denoted in the following table.

Prefix	Symbol(s)	Power of 10	Power of 2
yocto-	y	10^{-24} *	—
zepto-	z	10^{-21} *	—
atto-	a	10^{-18} *	—
femto-	f	10^{-15} *	—
pico-	p	10^{-12} *	—
nano-	n	10^{-9} *	—
micro-	m	10^{-6} *	—
milli-	m	10^{-3} *	—
centi-	c	10^{-2} *	—
deci-	d	10^{-1} *	—
(none)	—	10^0	2^0
deka-	D	10^1 *	—
hecto-	h	10^2 *	—
kilo-	k or K **	10^3	2^{10}
mega-	M	10^6	2^{20}
giga-	G	10^9	2^{30}
tera-	T	10^{12}	2^{40}
peta-	P	10^{15}	2^{50}
exa-	E	10^{18} *	2^{60}
zetta-	Z	10^{21} *	2^{70}
yotta-	Y	10^{24} *	2^{80}

* Not generally used to express data speed

** k = 10^3 and K = 2^{10}

Examples of quantities or phenomena in which power-of-10 prefix multipliers apply include frequency (including computer clock speeds), physical mass, power, energy, electrical voltage, and electrical current. Power-of-10 multipliers are also used to define binary data speeds. Thus, for example, 1 kbps (one kilobit per second) is equal to 10^3 , or 1,000, bps (bits per second); 1 Mbps (one megabit per second) is equal to 10^6 , or 1,000,000, bps. (The lowercase k is the technically correct symbol for kilo- when it represents 10^3 , although the uppercase K is often used instead.)

When binary data is stored in memory or fixed media such as a hard drive, diskette, ZIP disk, tape, or CD-ROM, power-of-2 multipliers are used. Technically, the uppercase K should be used for kilo- when it represents 2^{10} . Therefore 1 KB (one kilobyte) is 2^{10} , or 1,024, bytes; 1 MB (one megabyte) is 2^{20} , or 1,048,576 bytes.

The choice of power-of-10 versus power-of-2 prefix multipliers can appear arbitrary. It helps to remember that in common usage, multiples of bits are almost always expressed in powers of 10, while multiples of bytes are almost always expressed in powers of 2. Rarely is data speed expressed in bytes per second, and rarely is data storage or memory expressed in bits.

International System of Units

The International System of Units (abbreviated "SI" from the French version of the name) is a scientific method of expressing the magnitudes or quantities of seven important natural phenomena. This system was formerly called the meter-kilogram-second (MKS) system.

All SI units can be expressed in terms of standard multiple or fractional quantities, as well as directly. Multiple and fractional SI units are defined by prefix multipliers according to powers of 10 ranging from 10^{-24} to 10^{24} .

The **meter** (abbreviation, m) is the SI unit of displacement or length. One meter is the distance traveled by a ray of electromagnetic (EM) energy through a vacuum in $1/299,792,458$ ($3.33564095 \times 10^{-9}$) second. The meter was originally defined as one ten-millionth (0.0000001 or 10^{-7}) of the distance, as measured over the earth's surface in a great circle passing through Paris, France, from the geographic north pole to the equator.

The **kilogram** (abbreviation, kg) is the SI unit of mass. It is defined as the mass of a particular international prototype made of platinum-iridium and kept at the International Bureau of Weights and Measures. It was originally defined as the mass of one liter (10^{-3} cubic meter) of pure water.

The **second** (abbreviation, s or sec) is the SI unit of time. One second is the time that elapses during 9.192631770×10^9 cycles of the radiation produced by the transition between two levels of Cesium 133. It is also the time required for an EM field to propagate $299,792,458$ (2.99792458×10^8) meters through a vacuum.

The **Kelvin** (abbreviation K), also called the degree Kelvin (abbreviation, $^{\circ}\text{K}$), is the SI unit of temperature. One Kelvin is $1/273.16$ (3.6609×10^{-3}) of the thermodynamic temperature of the triple point of pure water (H_2O).

The **ampere** (abbreviation, A) is the SI unit of electric current. One ampere is the current that would produce a force of 0.0000002 (2×10^{-7}) newton between two straight, parallel, perfectly conducting wires having infinite length and zero diameter, separated by one meter in a vacuum. One ampere represents 6.24×10^{18} unit electric charge carriers, such as electrons, passing a specified fixed point in one second.

The **candela** (abbreviation, cd) is the SI unit of luminous intensity. It is the electromagnetic radiation, in a specified direction, that has an intensity of $1/683$ (1.46×10^{-3}) watt per steradian at a frequency of 540 terahertz (5.40×10^{14} hertz).

The mole (abbreviation, mol) is the SI unit of material quantity. One mole is the number of atoms in 0.012 kilogram of the most common isotope of elemental carbon (C-12). This is approximately 6.022169×10^{23} , and is also called the Avogadro constant.

These units are included in our **Table of Physical Units**.

See the *NIST Reference on Constants, Units, and Uncertainty* at <http://physics.nist.gov/cuu/Units/current.html>.

Table of Physical Units

This table shows, from the International System of Units, base and derived physical units, their shorthand symbols, and equivalent units in other unit systems. Many of the terms in the table are defined in this encyclopedia.

BASE UNITS

Quantity or phenomenon (and symbol)	Standard International unit (and symbol)	Alternate units (and symbols)
displacement (<i>d</i>)	meter (m)	centimeter (cm) foot (ft)
mass (<i>m</i>) weight (<i>w</i>)	kilogram (kg)	gram (g) pound (lb)
time (<i>t</i>)	second (s)	hour (hr) mean solar day (dy) synodic year (yr)
current (<i>I</i>)	ampere (A)	statampere (statA) abampere (abA)
temperature (<i>T</i>)	kelvin (°K or K)	degree Celsius (°C or C) degree Fahrenheit (°F or F) degree Rankine (°R or R)
amount of substance (<i>N</i>)	mole (mol)	—
luminous intensity (<i>B</i> or <i>L</i>)	candela (cd)	—

DERIVED UNITS

Quantity or phenomenon (and symbol)	Standard International unit (and symbol)	Alternate units (and symbols)
area (<i>A</i>)	meter squared (m ²)	centimeter squared (cm ²) circular mil foot squared (ft ²)
volume (<i>V</i>)	meter cubed (m ³)	centimeter cubed (cm ³) foot cubed (ft ³)
material density (<i>D</i>)	kilogram per meter cubed (kg/m ³ or kg · m ⁻³)	gram per centimeter cubed (g/cm ³ or g · cm ⁻³)
specific volume	meter cubed per kilogram (m ³ /kg or m ³ · kg ⁻¹)	centimeter cubed per gram (cm ³ /g or cm ³ · g ⁻¹)
amount of substance concentration	mole per meter cubed (mol/m ³ or mol · m ⁻³)	—
force (<i>F</i> or <i>F</i>)	newton (N)	dyne (dyn)
pressure stress	pascal (Pa)	dyne per centimeter squared (dyn/cm ² or dyn · cm ⁻²)
speed (<i>s</i>) velocity (<i>v</i> or <i>v</i>)	meter per second (m/s or m · s ⁻¹)	centimeter per second (cm/s or cm · s ⁻¹)
acceleration (<i>a</i> or <i>a</i>)	meter per second squared (m/s ² or m · s ⁻²)	centimeter per second squared (cm/s ² or cm · s ⁻²) gravity (g)
current density	ampere per meter squared (A/m ² or A · m ⁻²)	ampere per centimeter squared (A/cm ² or A · cm ⁻²)
electromotive force (emf) Voltage (<i>V</i> or <i>E</i>)	volt (V)	statvolt (statV) abvolt (abV)
resistance (<i>R</i>)	ohm (Ω)	statohm (statΩ) abohm (abΩ)
conductance (<i>G</i>)	siemens (S)	statsiemens (statS) absiemens (abS)
electric field strength (<i>E</i>)	volt per meter (V/m or V · m ⁻¹)	microvolt per meter (μV/m or μV · m ⁻¹)

DERIVED UNITS, *Continued...*

Quantity or phenomenon (and symbol)	Standard International unit (and symbol)	Alternate units (and symbols)
electric flux density	coulomb per meter squared (C/m ² or C · m ⁻²)	—
electric charge density	coulomb per meter cubed (C/m ³ or C · m ⁻³)	—
permittivity (ϵ)	farad per meter (F/m or F · m ⁻¹)	picofarad per meter (pF/m or pF · m ⁻¹)
power (P)	watt (W)	horsepower (hp) statwatt (statW) abwatt (abW)
energy (E)	joule (J)	erg (erg) watt hour (Wh) kilowatt hour (kWh)
magnetomotive force (M or mmf)	ampere-turn (AT)	gilbert (G)
charge quantity (Q)	coulomb (C)	statcoulomb (statC) abcoulomb (abC) faraday
capacitance (C)	farad (F)	statfarad (statF) abfarad (abF)
inductance (L)	henry (H)	stathenry (statH) abhenry (abH)
magnetic flux (Φ)	weber (Wb)	maxwell (Mx)
magnetic flux density	tesla (T)	gauss (G)
magnetic field strength (H)	ampere per meter (A/m or A · m ⁻¹)	oersted (Oe)
permeability (μ)	henry per meter (H/m or H · m ⁻¹)	microhenry per meter (μ H/m or μ H · m ⁻¹)
electromagnetic field strength	watt per meter squared (W/m ² or W · m ⁻²)	microwatt per meter squared (μ W/m ² or μ W · m ⁻²)
radiant intensity	watt per steradian (W/sr or W · sr ⁻¹)	lumen (lm)
luminance	candela per meter squared (cd/m ² or cd · m ⁻²)	candela per centimeter squared (cd/cm ² or cd · cm ⁻²)
luminous flux	lumen (lm)	watt per steradian (W/sr or W · sr ⁻¹)
illuminance	lux (lx)	watt per meter squared (W/m ² or W · m ⁻²)
plane angular measure	radian (rad)	degree (deg or °)
solid angular measure	steradian (sr)	—
angular speed (ω)	radian per second (rad/s or rad · s ⁻¹)	degree per second (deg/s or deg · s ⁻¹)
angular velocity (ω)	radian per second squared (rad/s ² or rad · s ⁻²)	degree per second squared (deg/s ² or deg · s ⁻²)
ionizing radiation	becquerel (Bq)	curie (cu)
absorbed ionizing radiation dose	gray (Gy)	rad (rad)
frequency (f or ν)	hertz (Hz)	kilohertz (kHz) megahertz (MHz) gigahertz (GHz) terahertz (THz)

DERIVED UNITS, *Continued...*

Quantity or phenomenon (and symbol)	Standard International unit (and symbol)	Alternate units (and symbols)
wavelength (λ)	meter (m)	centimeter (cm) millimeter (mm) nanometer (nm) Angström (Å)
wave number	reciprocal meter (m^{-1})	—
data quantity	bit (b) byte (B)	kilobit (kb) megabit (Mb) gigabit (Gb) kilobyte (KB) megabyte (MB) gigabyte (GB)
data speed bandwidth	bit per second (bps)	kilobit per second (kbps) megabit per second (Mbps) gigabit per second (Gbps) character per second (cps)

TYPES OF DSL

This table shows different kinds of Digital Subscriber Line (DSL) service.

DSL Type	Description	Data Rate Downstream; Upstream	Distance Limit	Application
IDSL	ISDN Digital	128 Kbps	18,000 feet on 24 gauge wire	Similar to the ISDN BRI service but data only (no voice on the same line)
CDSL	Consumer DSL from Rockwell	1 Mbps downstream; less upstream	18,000 feet on 24 gauge wire	Splitterless home and small business service; similar to DSL Lite
DSL Lite (same as G. Lite)	"Splitterless" DSL without the "truck roll"	From 256 Kbps to 6 Mbps downstream on the subscribed service	18,000 feet on 24 gauge wire	The standard ADSL; sacrifices speed for not having to install a splitter at the user's home or business
G.Lite (same as	"Splitterless" DSL without the "truck roll"	From 256 kbps to 6 Mbps, depending on the Subscribed service	18,000 feet on 24 gauge wire	The standard ADSL; sacrifices speed for not having to install a splitter at the user's home or business
HDSL	High bit-rate Digital Subscriber	1.544 Mbps duplex on two twisted-pair lines;	12,000 feet on 24 gauge wire	T1/E1 service between server and phone company or within a company; WAN, LAN, server access
SDSL	Symmetric DSL	1.544 Mbps duplex (U.S. and Canada); 2.048 Mbps Europe) on a single duplex line downstream and upstream	12,000 feet on 24 gauge wire	Same as for HDSL but requiring only one line of twisted-pair

TYPES OF DSL, *Continued...*

DSL Type	Description	Data Rate Downstream; Upstream	Distance Limit	Application
ADSL	Asymmetric Digital Subscriber Line	1.544 to 6.1 Mbps downstream; 16 to 640 Kbps upstream	1.544 Mbps at 18,000 feet; 2.048 Mbps at 16,000 feet; 6.312 Mbps at 12,000 feet; 8.448 Mbps at 9,000 feet	Used for Internet and Web access, motion video, video on demand remote LAN access
RADSL	Rate-Adaptive DSL from Westell	Adapted to the line, 640 Kbps to 2.2 Mbps to 1.088 Mbps upstream	Not provided	Similar to ADSL
UDSL	Unidirectional DSL proposed by a company in Europe	Not known	Not known	Similar to HDSL
VDSL	Very high digital Subscriber Line	12.9 to 52.8 Mbps downstream; 1.5 to 2.3 Mbps upstream; 1.6 Mbps to 2.3 Mbps downstream	4,500 feet at 12.96 Mbps; 3,000 feet at 25.82 Mbps; 1,000 feet at 51.84 Mbps	ATM networks; Fiber to the Neighborhood

TYPES OF RAM

This table summarizes many types of random access memory (RAM).

RAM Technology	Application and Computer Location	Access Speed Range	Ports	Characteristic
Static RAM (SRAM)	Level-1 and level-2 cache memory Also used in RAMDAC	Fast	One	RAM that is continually charged More expensive than DRAM
Burst SRAM (BSRAM)	Level-2 cache memory	Fast	One	SRAM inburst mode
DRAM	Main memory Low-cost video	Slow	One	A generic term for any kind dynamic (constantly recharged) RAM
FPM (Fast page Mode) DRAM	Main memory low-cost video memory	slow	One	Prior to EDO DRAM, the most common type of DRAM
EDO (Extended Data Out)	Main memory low-cost video	5-20% faster than FPM DRAM	One	Uses overlapping reads (one can begin while another is finishing). Currently, the most common type of DRAM
BEDO (Burst Extended Data DRAM)	Main memory and low-cost video	Faster than EDO DRAM 4-1-1-1 at 66 MHz	One	Not widely used because not supported by processor chipset makers
EDRAM Enhanced DRAM	Level-2 cache memory	15 ns access to SRAM 35 ns access to DRAM	One	Contains a 256-byte SRAM inside a larger DRAM

RAM Technology	Application and Computer Location	Access Speed Range	Ports	Characteristic
Nonvolatile RAM	Preset phone numbers and profiles in modems	Fast	One	Battery-powered RAM
Synchronous DRAM (SDRAM)	Main memory	See specific forms of SDRAM	One	Generic term for DRAMS with a synchronous interface
JEDEC Synchronous DRAM (JEDEC SDRAM)	Main memory	Intended to run at	One	An Intel specification designed to work with their i440 BX
PC100 Synchronous DRAM (PC100 SDRAM)	Main memory	Intended to run at	One	An Intel specification designed to work with their i440BX
Double Data Rate Synchronous DRAM (DDR DRAM)	Main memory	Up to 200 MHz	One	Activates output on both the up and the down part of the clock cycle, doubling the DATA RATE OF PC100 SDRAM
Enhanced Synchronous DRAM	Main memory	Fast (100 MHz +)	Two	Twice as fast as SDRAM
SyncLink DRAM (SLDRAM)	Main memory	Fastest (200 MHz +)	One	Open protocol-based design Uses "packets" for address, data, and control signals
Direct Rambus DRAM (DRDRAM)	Main memory	Up to 800 MHz but with a 16-bit bus width	One	Backed by Intel and Rambus
Ferroelectric RAM	Main memory in			Developed by Ramtron
RAMDAC	Video Card	Fast	One	Uses a small SRAM to store the color palette table used to provide data for digital-to-analog conversion
Rambus DRAM (RDRAM)	Video memory for Nintendos	Up to 600 MHz	One	Intel and Rambus architecture
Synchronous Graphics RAM	Moderate to high-end video memory	Closer to VRAM than DRAM	One	Has special performance enhancing features Example: Matrox Mystique
VRAM (Video RAM)	Higher-cost video memory	Twice the speed of DRAM	Two	Dual-ported, meaning a new image can be stored in RAM while a previous image is being sent to the display
WRAM (Window RAM)	Less expensive video memory	25% faster than VRAM	Two	With RAMDAC , can handle true color at 1600 by 1200 pixel resolution
Multibank DRAM (MDRAM)	Low-cost high-end video memory	Faster	One	Interleaved memory accesses between banks Memory has multiple 32 kilobyte banks that can be accessed independently Can be manufactured to fit the amount of memory the card requires. No size-related performance penalty

TYPES OF CD AND DVD

Drive Type	"Read" & "Write" Capability
CD (CD player)	Reads audio CD only
CD-ROM (Compact Disc-Read Only Memory)	Reads audio CD, CD-ROM, CD-R, Photo CD
CD-ROM multiread (Compact Disc-Read Only Memory, Multiread)	CD-ROM, CD-R, CD-RW, CD-i, Photo CD
CD-R (Compact Disc-Recordable)	Reads CD-ROM and CD-R, some read CD-RW (Writes once on CD-R discs)
CD-RW (Compact Disc-Rewritable)	Reads CD-ROM, CD-R, and CD-RW (Writes and rewrites on CD-RW discs)
DVD-RAM (Digital Versatile Disc-Random-Access-Memory)	Reads all CD formats. Reads DVD ROM. Reads and writes DVD discs.

CD AND DVD DATA TRANSFER RATES AND RPMs

Optical Media Drive Speed	Maximum Data Transfer Rate	RPMs (revolutions per minute)
1X CD-ROM	150 KB/sec	200–530
2X CD-ROM	300 KB/sec	400–1060
4X CD-ROM	600 KB/sec	800–2120
8X 12X CD-ROM	1.2 MB/sec	1600–4240
24X 50X	1.8–6 MB/sec	2400–6360 approximately
1X DVD-ROM	1.25 MB/sec	No exact data, but much slower than 1X CD-ROM

Favorite Technology Quotations

Where is all the knowledge we lost with information?

—T.S. Elliot

The telephone wire, as we know it, has become too slow and too small to handle Internet traffic. It took 75 years for telephones to be used by 50 million customers, but it took only four years for the Internet to reach that many users.

—Lori Valigra

640K ought to be enough for anybody.

—Microsoft Chairman Bill Gates, 1981

The real problem is not whether machines think but whether men do.

—B. F. Skinner

There are three roads to ruin; women, gambling and technicians. The most pleasant is with women, the quickest is with gambling, but the surest is with technicians.

—George Pompidou

Technology is dominated by two types of people: those who understand what they do not manage, and those who manage what they do not understand.

—Anonymous

Computers make it easier to do a lot of things, but most of the things they make it easier to do don't need to be done.

—Andy Rooney

I think there is a world market for maybe five computers.

—IBM Chairman Thomas Watson, 1943

If you have any trouble sounding condescending, find a Unix user to show you how it's done.

—Scott Adams

In a few minutes a computer can make a mistake so great that it would have taken many men many months to equal it.

—Anonymous

If computers get too powerful, we can organize them into a committee. That will do them in.

—Bradley's Bromide

The Internet is the Viagra of big business.

—Jack Welch, Chairman and CEO, General Electric

There are two major products that came out of Berkeley: LSD and UNIX. We don't believe this to be a coincidence.

—Jeremy S. Anderson

One machine can do the work of fifty ordinary men. No machine can do the work of one extraordinary man.

—Elbert Hubbard

Any teacher that can be replaced by a computer, deserves to be.

—**David Thornburg**

Those parts of the system that you can hit with a hammer are called hardware; those program instructions that you can only curse at are called software.

—**Anonymous**

We live in a society exquisitely dependent on science and technology, in which hardly anyone knows anything about science and technology.

—**Carl Sagan**

If you tried to read every document on the web, then for each day's effort you would be a year further behind in your goal.

—**Anonymous**

There might be new technology, but technological progress itself was nothing new - and over the years it had not destroyed jobs, but created them.

—**Margaret Thatcher**

The most overlooked advantage to owning a computer is that if they foul up there's no law against whacking them around a little.

—**Porterfield**

Everything that can be invented has been invented.

—**Charles H. Duell, Commissioner, U.S. Office of Patents, 1899**

Computers are magnificent tools for the realization of our dreams, but no machine can replace the human spark of spirit, compassion, love, and understanding.

—**Louis Gerstner, CEO, IBM**

GARBAGE IN—GOSPEL OUT

—**Fairchild Research and Development, 1969**

Any science or technology which is sufficiently advanced is indistinguishable from magic.

—**Arthur C. Clarke**

Never let a computer know you're in a hurry.

—**Anonymous**

A year spent in artificial intelligence is enough to make one believe in God.

—**Alan J. Perlis**

I have not failed. I've just found 10,000 ways that won't work.

—**Thomas Edison**

Get your feet off my desk, get out of here, you stink, and we're not going to buy your product.

—**Joe Keenan, President of Atari, in 1976**

Responding to Steve Jobs' offer to sell him rights to the new personal computer he and Steve Wozniak developed

The Internet is a great way to get on the net.

—**Senator Bob Dole**

Computers in the future may have only 1,000 vacuum tubes and perhaps only weigh 1 1/2 tons.

—**Popular Mechanics, 1949**

From then on, when anything went wrong with a computer, we said it had bugs in it.

—**Rear Admiral Grace Murray Hopper, U.S. Navy**

Technology is like fish. The longer it stays on the shelf, the less desirable it becomes.

—**Andrew Heller, IBM**

AOL is like the cockroach left after the nuclear bomb hits. They know how to survive.

—**Jan Horsfall, VP of marketing for Lycos**

How could this be a problem in a country where we have Intel and Microsoft?

—**Al Gore on Y2K**

The modern computer hovers between the obsolescent and the nonexistent.

—**Sydney Brenner in 1927**

The Linux philosophy is 'Laugh in the face of danger'. Oops. Wrong One. 'Do it yourself'. Yes, that's it.

—**Linus Torvalds**

Windows is just DOS in drag.

—**Anonymous**

There is no reason for any individual to have a computer in their home.

—**Ken Olson (President of Digital Equipment Corporation) at the Convention of the World Future Society in Boston in 1977**

During my service in the United States Congress, I took the initiative in creating the Internet.

—**Al Gore describing his 1986 legislation to interconnect five supercomputer centers (17 years after the first Internet servers hooked up)**

The day I made that statement, I was tired because I'd been up all night inventing the Camcorder.

—**Al Gore attempting damage control**

10BASE-2

10BASE-2, one of several physical media specified by **IEEE 802.3** for use in an **Ethernet** local area network (**LAN**), consists of **Thinwire coaxial cable** with a maximum segment length of 185 meters. Like other specified media, 10BASE-2 supports Ethernet’s 10 **Mbps** data rate.

In addition to 10BASE-2, 10 megabit Ethernet can be implemented with these media types:

- 10BASE-5 (**Thickwire** coaxial cable with a maximum segment length of 500 meters)
- 10BASE-F (**optical fiber** cable)
- 10BASE-T (ordinary telephone **twisted pair** wire)
- 10BASE-36 (broadband multi-channel coaxial cable with a maximum segment length of 3,600 meters)

This designation is an Institute of Electrical and Electronics Engineers (**IEEE**) shorthand identifier. The “10” in the media type designation refers to the transmission speed of 10 Mbps. The “BASE” refers to baseband signalling, which means that only Ethernet signals are carried on the medium (or, with 10BASE-36, on a single channel). The “T” represents twisted-pair; the “F” represents fiber optic cable; and the “2”, “5”, and “36” refer to the coaxial cable segment length (the 185 meter length has been rounded up to “2” for 200).

Also see **100BASE-T** and **Gigabit Ethernet**.

10BASE-5

10BASE-5, one of several physical media specified by **IEEE 802.3** for use in an **Ethernet** local area network (**LAN**), consists of **Thickwire coaxial cable** with a maximum segment length of 500 meters. Like other specified media, 10BASE-2 supports Ethernet’s 10 **Mbps** data rate.

In addition to 10BASE-5, 10 megabit Ethernet can be implemented with these media types:

- 10BASE-2 (**Thinwire** coaxial cable with a maximum segment length of 185 meters)
- 10BASE-F (**optical fiber** cable)
- 10BASE-T (ordinary telephone **twisted pair** wire)
- 10BASE-36 (broadband multi-channel coaxial cable with a maximum segment length of 3,600 meters)

This designation is an Institute of Electrical and Electronics Engineers (**IEEE**) shorthand identifier. The “10” in the media type designation refers to the transmission speed of 10 Mbps. The “BASE” refers to baseband signalling, which

means that only Ethernet signals are carried on the medium (or, with 10BASE-36, on a single channel). The “T” represents twisted-pair; the “F” represents fiber optic cable; and the “2”, “5”, and “36” refer to the coaxial cable segment length (the 185 meter length has been rounded up to “2” for 200).

Also see **100BASE-T** and **Gigabit Ethernet**.

10BASE-36

10BASE-36 is a type of physical cabling defined in the **IEEE 802.3 (Ethernet)** standard for **broadband** application. Although Ethernet is inherently a **baseband** system, 10BASE-36 specifies the use of a 10-megahertz signal on each channel within a 75-ohm coaxial broadband cable so that bandwidth is effectively expanded. Each channel requires 3 pairs of wires in the **coaxial cable**. Baseband differential phase-shift keying (**PSK**) is used to modulate the signal on each channel. Each channel has a transmission speed of 10 **Mbps**. The cable can extend for up to 3,600 meters.

10BASE-F

10BASE-F, one of several physical media specified by **IEEE 802.3**, is the use of **optical fiber** in an **Ethernet** local area network (**LAN**). Like other specified media, 10BASE-F supports Ethernet’s 10 **Mbps** data rate.

In addition to 10BASE-F, 10 megabit Ethernet can be implemented with these media types:

- 10BASE-2 (**Thinwire** coaxial cable with a maximum segment length of 185 meters)
- 10BASE-5 (**Thicknet** coaxial cable with a maximum segment length of 500 meters)
- 10BASE-T (ordinary telephone **twisted pair** wire)
- 10BASE-36 (broadband multi-channel coaxial cable with a maximum segment length of 3,600 meters)

This designation is an Institute of Electrical and Electronics Engineers (**IEEE**) shorthand identifier. The “10” in the media type designation refers to the transmission speed of 10 Mbps. The “BASE” refers to baseband signalling, which means that only Ethernet signals are carried on the medium (or, with 10BASE-36, on a single channel). The “T” represents twisted-pair; the “F” represents fiber optic cable; and the “2”, “5”, and “36” refer to the coaxial cable segment length (the 185 meter length has been rounded up to “2” for 200).

10BASE-T

10BASE-T, one of several physical media specified in the **IEEE 802.3** standard for **Ethernet** local area networks (LANs), is ordinary telephone **twisted pair** wire. 10BASE-T supports Ethernet's 10 **Mbps** transmission speed. In addition to 10BASE-T, 10 megabit Ethernet can be implemented with these media types:

- 10BASE-2 (Thinwire **coaxial cable** with a maximum segment length of 185 meters)
- 10BASE-5 (Thickwire coaxial cable with a maximum segment length of 500 meters)
- 10BASE-F (**optical fiber** cable)
- 10BASE-36 (broadband coaxial cable carrying multiple baseband channels for a maximum length of 3,600 meters)

This designation is an Institute of Electrical and Electronics Engineers (**IEEE**) shorthand identifier. The "10" in the media type designation refers to the transmission speed of 10 Mbps. The "BASE" refers to baseband signalling, which means that only Ethernet signals are carried on the medium. The "T" represents twisted-pair; the "F" represents fiber optic cable; and the "2", "5", and "36" refer to the coaxial cable segment length (the 185 meter length has been rounded up to "2" for 200).

Also see **100BASE-T** and **Gigabit Ethernet**.

100BASE-T

In 100 **Mbps** (megabits per second) **Ethernet** (known as **Fast Ethernet**), there are three types of physical wiring that can carry signals:

- 100BASE-T4 (four pairs of telephone **twisted pair** wire)
- 100BASE-TX (two pairs of data grade twisted-pair wire)
- 100BASE-FX (a two-strand **optical fiber** cable)

This designation is an **Institute of Electrical and Electronics Engineers** shorthand identifier. The "100" in the media type designation refers to the transmission speed of 100 Mbps. The "BASE" refers to baseband signalling, which means that only Ethernet signals are carried on the medium. The "T4," "TX," and "FX" refer to the physical medium that carries the signal. (Through repeaters, media segments of different physical types can be used in the same system.)

The TX and FX types together are sometimes referred to as "100BASE-X." (The designation for "100BASE-T" is also sometimes seen as "100BaseT.")

1000BASE-T

1000BASE-T is **Gigabit Ethernet** (1 **gigabit** is 1000 **megabits** per second) on copper cables, using four pairs of **Category 5 unshielded twisted pair** to achieve the gigabit data rate. 1000BASE-T can be used in data centers for server switching, for uplinks from desktop computer switches, or directly to

the desktop for **broadband** applications. A big advantage of 1000BASE-T is that existing copper cabling can be used instead of having to rewire with optical fiber.

For Gigabit Ethernet, industry offerings include these types of wiring:

- 1000BASE-SX (a short **laser wavelength** on multimode **fiber optic** cable for a maximum length of 550 meters)
- 1000BASE-LX/LH (a long wavelength for a "long haul" fiber optic cable for a maximum length of 10 kilometers)
- 1000BASE-ZX (an extended wavelength single-mode optical fiber for up to 100 kilometers)
- 1000BASE-CX (two pairs of 150-ohm **shielded twisted pair** cable for a maximum length of 25 meters)
- 1000BASE-T (four pairs of **Category 5 unshielded twisted pair** cable for a maximum length of 100 meters)

The 1000BASE designation is an **IEEE** shorthand identifier. The "1000" in the media type designation refers to the transmission speed of 1000 Mbps. The "BASE" refers to baseband signalling, which means that only Ethernet signals are carried on the medium. (Through repeaters, media segments of different physical types can be sometimes be used in the same system.)

The designation for "1000BASE-T" is also sometimes seen as "1000BaseT."

10-Gigabit Ethernet

10-Gigabit Ethernet, being standardized in **IEEE 802.3a**, is a developing telecommunication technology that offers data speeds up to 10 billion bits per second. Built on the **Ethernet** technology used in most of today's local area networks (LANs), 10-Gigabit Ethernet is described as a "disruptive" technology that offers a more efficient and less expensive approach to moving data on **backbone** connections between networks while also providing a consistent technology end-to-end. Using **optical fiber**, 10-Gigabit Ethernet can replace existing networks that use **ATM switches** and **SONET multiplexers** on an **OC-48** SONET ring with a simpler network of 10-Gigabit Ethernet switches and at the same time improve the data rate from 2.5 **Gbps** to 10 Gbps.

10-Gigabit Ethernet is expected to be used to interconnect local area networks (LANs), wide area networks (**WANs**), and metropolitan area networks (**MANs**). 10-Gigabit Ethernet uses the familiar **IEEE 802.3** Ethernet **media access control** (MAC) protocol and its **frame** format and size. Like **Fast Ethernet** and **Gigabit Ethernet**, 10-Gigabit Ethernet uses **full-duplex** transmission, which makes possible a considerable distance range. On **multimode fiber**, 10-Gigabit Ethernet will support distances up to 300 **meters**; on **single mode fiber**, it will support distances up to 40 kilometers. Smaller Gigabit Ethernet networks can feed into a 10-Gigabit Ethernet network.

10-high-day busy period

In designing and assessing **networks**, the peak load is sometimes measured using the 10HD (10-high-day) busy period method. The 10HD busy period is the average of the amount of traffic during the busiest hour of the 10 days during the year when the overall traffic is heaviest.

Another index to peak traffic is the average bouncing busy hour (**ABBH**).

121

In Internet **e-commerce**, 121 is short for *one-to-one*, the philosophy that treating each customer as a special individual is a more successful approach than treating customers as a group of similar individuals.

1170

“Spec 1170” was the working name of the standard **UNIX** programming interface specification that is now known as *X/Open Programming Guide 4.2 (XPG 4.2)*. The specification has also been known as the “Single UNIX Specification” and, most recently, as “UNIX 98.” In the “Spec 1170” or first version of the Single UNIX Specification, there were 1,170 **C** language functions or individual instructions.

The Single UNIX Specification is maintained by **The Open Group**, which certifies implementations and provides UNIX product branding following conformance assurance and testing.

1284

The IEEE 1284 parallel interface standard is the prevalent standard for connecting a computer to a printer or certain other devices over a **parallel** (eight bits of data at a time) physical and electrical **interface**. The physical connection is similar to the older Centronics interface, which it continues to support. Whereas the Centronics interface only allowed data to flow in one direction, from computer to peripheral, IEEE 1284 also supports bi-directional data flow.

When the Centronics parallel interface was first developed, the main peripheral was the printer. Since then, portable disk drives, **tape** drives, and **CD-ROM** players are among devices that have adopted the parallel interface. These new uses caused manufacturers to look at new ways to make the Centronics parallel interface better. In 1991, Lexmark, IBM, Texas Instruments, and others met to discuss a standard that would offer more speed and bi-directional communication. Their effort and the sponsorship of the Institute of Electrical and Electronics Engineers (**IEEE**) resulted in the IEEE 1284 committee. The IEEE 1284 standard was approved for release in March 1994.

The IEEE 1284 standard specifies five modes of operation, each mode providing data transfer in either the forward direction (computer to peripheral), backward direction (peripheral to computer), or bi-directional (one direction at a time).

- **Compatibility mode** is the original Centronics parallel interface and is intended for use with dot matrix printers and older laser printers. The compatibility mode can be combined with the nibble mode for bi-directional data transfer.
- **Nibble mode** allows data transfer back to the computer. The nibble mode uses the status lines to send 2 **nibble** (4-bit units) of data to the computer in two data transfer cycles. This mode is best used with printers.
- **Byte mode** uses software drivers to disable the drivers that control the data lines in order for data to be sent from the printer to the computer. The data is sent at the same speed as when data is sent from the computer to the printer. One byte of data is transferred instead of the two data cycles required by the nibble mode.
- **ECP mode** (Enhanced Capability Port mode) is an advanced bi-directional mode for use with printers and scanners. It allows data **compression** for images, **FIFO** (first in, first out) for items in a **queue**, and high-speed, bi-directional communication. Data transfer occurs at two to four megabytes per second. An advanced feature is **channel** addressing. This is used for multifunction devices such as printer/fax/modem devices. For example, if a printer/fax/modem device needs to print and send data over the **modem** at the same time, the channel address software driver of the ECP mode assigns a new channel to the modem so that both devices can work simultaneously.
- **EPP mode** (Enhanced Parallel Port mode) was designed by Intel, Xircom, and Zenith Data Systems to provide a high-performance parallel interface that could also be used with the standard interface. EPP mode was adopted as part of the IEEE 1284 standard. The EPP mode uses data cycles that transfer data between the computer and the peripheral and address cycles that assign address, channel, or command information. This allows data transfer speeds of 500 kilobytes to 2 megabytes per second, depending on the speed of the slowest interface. The EPP mode is bi-directional. It is suited for network adapters, data acquisition, portable hard drives, and other devices that need speed.

The computer must determine what the capabilities of the attached peripheral are and which mode to utilize. The concept developed to determine these factors is called negotiation. Negotiation is a sequence of events on the parallel port interface that determines which IEEE 1284 modes the device can handle. An older device will not respond to the negotiation sequence and compatibility mode

#

is selected to operate that device. A newer device will respond to the negotiation sequence and a more advanced mode can be set.

2.5G

2.5G describes the state of **wireless** technology and capability usually associated with General Packet Radio Services (**GPRS**)—that is, between the second and third generations of wireless technology. The second generation or **2G**-level of wireless is usually identified as Global System for Mobile (**GSM**) service and the third generation or **3G**-level is usually identified as Universal Mobile Telecommunication Service (**UMTS**). Each generation provides a higher data rate and additional capabilities. There is also a fourth generation (**4G**) of technology in the planning and research stages.

GPRS offers data speeds at 28 **Kbps** (and possibly higher) and is expected to be introduced in the 2001 through 2003 timeframe.

2000

The year 2000 (also known as "Y2K") raised questions for anyone who depended on a program in which the year was represented by a two-digit number, such as "97" for 1997. Many programs written years ago (when storage limitations encouraged such information economies) are still being used. The problem was that when the two-digit space allocated for "99" rolled over to 2000, the next number was "00." Frequently, program logic assumes that the year

X,Y,Z

number gets larger, not smaller—so "00" was anticipated to wreak havoc in a program that hadn't been modified to account for the millennium.

So pervasive was the problem in the world's **legacy application** payroll, billing, and other programs that a new industry sprang up dedicated to helping companies solve the problem. IBM and other major computer manufacturers, software houses, and consultants offered tools and services to address this problem.

2001

Midnight **UTC** on January 1, 2001 marked the beginning of the third **millennium** on the Western world's **Gregorian calendar**. *2001* is also the name of the 1968 movie, written by Arthur C. Clarke and directed by Stanley Kubrick, that shaped views of the future for several decades, especially about what future computers might be like. HAL (officially HAL 9000) is the human-like computer that manages the spaceship in the movie. HAL (the script says that HAL stands for "Heuristically Programmed ALgorithmic computer" but the letters in the name are one letter away from "IBM") is programmed to think and talk like a human being, an **artificial intelligence** combining people skills with ruthless calculation. As the movie became part of history and the real 2001 approached, new views of technology tended toward the envisionment of a globally networked "intelligence" for which William Gibson's **matrix** in his fictional *Neuromancer* and the real **World Wide Web** seemed to be harbingers.

24/7

See "24x7"

24X

See "X (compact disc access time)"

24x7

24x7 means "24 hours a day, 7 days a week" and is used to describe a service, such as computer **server** monitoring, that is continuous, is always available (day or night), or involves products that can run constantly without disruption or *downtime*.

2600

2600 is the frequency in **hertz** (cycles per second) that AT&T formerly put as a steady **signal** on any long-distance telephone line that was not currently in use. Prior to widespread use of *out-of-band signaling*, AT&T used *in-band signaling*, meaning that signals about telephone connections were transmitted on the same line as the voice conversations. Since no signal at all on a line could indicate a pause in a voice conversation, some other way was needed for the phone company to know when a line was free for use. So

AT&T put a steady 2600 hertz signal on all free lines. Knowing this, certain people developed a way to use a whistle or other device to generate a 2600 hertz tone on a line that was already in use, making it possible to call anywhere in the world on the line without anyone being charged. Cracking the phone system became a hobby for some in the mostly under-20 set who came to be known as **phreaks**.

In the 1960s, a breakfast cereal named Captain Crunch included a free premium: a small whistle that generated a 2600 hertz signal. By dialing a number and then blowing the whistle, you could fool the phone company into thinking the line was not being used while, in fact, you were now free to make a call to any destination in the world.

Today, long-distance companies use Signaling System 7, which puts all **channel** signals on a separate signaling channel, making it more difficult to break into the phone system.

3270

The 3270 Information Display System, a product from IBM, was, prior to the arrival of the PC, the way that almost the entire corporate world interfaced with a computer. In its day (the early 1970s), a 3270 display terminal was considered a vast improvement over its predecessor, the 2260.

The 3277 terminal was a non-graphical (text only) monochrome (black screen with green letters) display that **buffered** data so that key strokes could be saved until the ENTER key was pressed. (Previous terminals sent every key stroke immediately to the computer to which the terminal was attached.) The 3277 was also *field-oriented* rather than *line-oriented* which meant that a program could write an output data stream to the terminal based on application-oriented fields rather than having to create the display output line by line. A number of 3277s could be attached to a control unit or cluster controller which in turn was attached to an IBM **mainframe** computer. Terminals could be attached to the computer on a relatively high-bandwidth local link called a **channel** or “remotely” over a telecommunication link that was either dedicated (leased) or dial-up.

After the **personal computer** arrived with its own self-sufficient operating system and applications, it gradually replaced the 3270 system in much of the corporate world (although there are almost certainly are some working 3270s in use as this is being written). A 3270 terminal became the most prominent example of what became known as a “dumb terminal,” since it relied entirely on its attachment to a mainframe (and sometimes a **minicomputer**) for its “brains.” The PC attached to a mainframe then became known generically as an “intelligent workstation.” It could run its own programs independently of the mainframe and it could also interface with mainframe applications. There was one product attempt to blend the two, called the 3270 PC.

The terminals themselves were the 3277 (which attached to a control unit), a 3275 standalone terminal (for locations where only a single terminal was needed), the 3278 (a sleeker version of the 3277), and the 3279 color terminal. The control units were the 3271 (channel attachment), 3272 (telecommunication attachment), and the 3274 (a control unit with a smaller form factor that could handle up to 32 terminals). For about 15 years, the 3270 family, one of IBM’s most successful products ever, was a ubiquitous feature of offices the world over. The PC changed all that.

However, many thousands of corporate **legacy application** programs written to interact with users at 3270s are being used from PCs equipped with software known generally as *3270 emulation*. TN3270 is a program that provides PC users remote (**Telnet**) connection to an IBM computer that is running 3270 applications.

3-D

In computers, 3-D (three dimensions or three-dimensional) describes an image that provides the perception of depth. When 3-D images are made interactive so that users feel involved with the scene, the experience is called **virtual reality**. You usually need a special **plug-in** viewer for your Web browser to view and interact with 3-D images. Virtual reality experiences may also require additional equipment.

3-D image creation can be viewed as a three-phase process of tessellation, geometry, and rendering. In the first phase, models are created of individual objects using linked points that are made into a number of individual polygons (tiles). In the next stage, the polygons are transformed in various ways and lighting effects are applied. In the third stage, the transformed images are rendered into objects with very fine detail.

Popular products for creating 3-D effects include Extreme 3D, LightWave 3D, Ray Dream Studio, 3D Studio MAX, Softimage 3D, and Visual Reality. The Virtual Reality Modelling Language (**VRML**) allows the creator to specify images and the rules for their display and interaction using textual language statements.

3-D browser

A 3-D browser is a Web **browser** that allows the viewer to view and interact with six Web pages at a time by creating a virtual room on the viewer's screen. Instead of opening six Web pages, minimizing your screen and toggling back and forth between pages, imagine you are standing inside a six-sided cube and each side of the cube is displaying a Web page. There is a Web page in front of you, a Web page on each side of you, a page above you, a page below you and a page behind you. You can use your cursor to rotate the cube and put any side of the cube directly in front of you. Links on all the pages are active, so you can click from page to page and change the "walls" of your virtual Web room. If you see something that catches your interest, you can use the zoom feature to enlarge the "wall" so that it becomes a traditional page viewed on your flat screen.

The concept of a 3-D Web browser has been promoted by former architect and chief executive officer of 2ce, Mike Rosen. Rosen hopes that the next generation of computer users, who have grown up multi-tasking in virtual reality gaming environments, will embrace a 3-D version of the Web. Besides being fun, Rosen believes that having the ability to view multiple pages will be of practical use to day traders and others whose occupations require them to view multiple Web pages throughout the day.

3G

Also see **UMTS**.

3G is a short term for third-generation wireless, and refers to near-future developments in personal and business **wireless** technology, especially mobile communications. This phase is expected to reach maturity between the years 2003 and 2005.

The third generation, as its name suggests, follows the first generation (1G) and second generation (2G) in wireless communications. The 1G period began in the late 1970s and lasted through the 1980s. These systems featured the first true mobile phone systems, known at first as "cellular mobile radio telephone." These networks used **analog** voice signaling, and were little more sophisticated than repeater networks used by **amateur radio** operators. The 2G phase began in the 1990s, and much of this technology is still in use. The 2G cell phone features **digital** voice encoding. Examples include **CDMA**, **TDMA**, and **GSM**. Since its inception, 2G technology has steadily improved, with increased **bandwidth**, **packet** routing, and the introduction of multimedia. The present state of mobile wireless communications is often called 2.5G.

Ultimately, 3G is expected to include capabilities and features such as

- Enhanced multimedia (voice, data, video, and remote control)
- Usability on all popular modes (cellular telephone, e-mail, paging, fax, videoconferencing, and Web browsing)
- Broad bandwidth and high speed (upwards of 2 Mbps)
- Routing flexibility (repeater, satellite, LAN)
- Operation at approximately 2 GHz transmit and receive frequencies
- Roaming capability throughout Europe, Japan, and North America

While 3G is generally considered applicable mainly to mobile wireless, it is also relevant to **fixed wireless** and portable wireless. The ultimate 3G system might be operational from any location on, or over, the earth's surface, including use in or by

- Homes
- Businesses
- Government offices
- Medical establishments
- The military
- Personal and commercial land vehicles
- Private and commercial watercraft and marine craft
- Private and commercial aircraft (except where passenger use restrictions apply)
- Portable (pedestrians, hikers, cyclists, campers)
- Space stations and spacecraft

Proponents of 3G technology promise that it will "keep people connected at all times and in all places."

3-tier application

A 3-tier application is an **application** program that is organized into three major parts, each of which is **distributed** to a different place or places in a network. The three parts are

- The workstation or presentation interface
- The business logic
- The database and programming related to managing it

In a typical 3-tier application, the application user's workstation contains the programming that provides the graphical user interface (GUI) and application-specific entry forms or interactive windows. (Some data that is local or unique for the workstation user is also kept on the local hard disk.)

Business logic is located on a local area network (LAN) server or other shared computer. The business logic acts as the server for client requests from workstations. In turn, it determines what data is needed (and where it is located) and acts as a client in relation to a third tier of programming that might be located on a **mainframe** computer.

The third tier includes the **database** and a program to manage read and write access to it. While the organization of an application can be more complicated than this, the 3-tier view is a convenient way to think about the parts in a large-scale program.

A 3-tier application uses the **client/server** computing model. With three tiers or parts, each part can be developed concurrently by different team of programmers coding in different languages from the other tier developers. Because the programming for a tier can be changed or relocated without affecting the other tiers, the 3-tier model makes it easier for an enterprise or software packager to continually evolve an application as new needs and opportunities arise. Existing applications or critical parts can be permanently or temporarily retained and encapsulated within the new tier of which it becomes a component.

42

42 is the number from Douglas Adams' *The Hitchhiker's Guide to the Galaxy* from which all meaning ("the meaning of life, the universe, and everything") could be derived.

A BBC radio script based on Adams' book contains the following lines:

("Cave man" lays out following sentence in Scrabble stones: "What do you get if you multiply six by nine?")

Arthur: Six by nine? Forty-two? You know, I've always felt that there was something fundamentally wrong with the Universe.

(Faint and distant voice:) Base thirteen!

For the literal-minded and those unfamiliar with terms like "base thirteen," this is a number system in which the number 10 is equivalent to our more familiar decimal 13. A base-13 number 42, therefore, is the same as four 13s plus 2, or decimal 54. So "six by nine" (six times nine) or decimal 54 is, in base 13, 42. For the mystically inclined, 42 in base 13 is the same as 110110 in binary (base 2). This could mean almost anything, and many Adams fans have spent untold hours discovering all of the places where the number "42" pops up. For example, there are many mentions of the number in the Book of Revelations. Others have made a game of finding 42s, such as these:

- The angle at which light reflects off of water to create a rainbow is 42 degrees.
- Two physical constants in the universe are the speed of light and the diameter of a proton. It takes light 10 to the minus 42nd power seconds to cross the diameter of a proton.
- A barrel holds 42 gallons.

(It should be noted that all of these 42's are base 10, not base 13.)

404

Also see **errors**.

404 is a frequently-seen status code that tells a Web user that a requested page is "Not found." 404 and other status codes are part of the Web's Hypertext Transfer Protocol (**HTTP**), written in 1992 by the Web's inventor, Tim Berners-Lee. He took many of the status codes from the earlier Internet protocol for transferring files, the File Transfer Protocol (**FTP**).

What to Do If You Get a 404

If the site no longer exists, there's nothing you can do. However, it only takes one mistyped character to result in a 404. See whether the ".htm" should be an ".html" or vice versa. If you're linking from a Web site, you can do a "View source" to make sure it wasn't miscoded. Whether or not it is, you may want to send a note to the Webmaster so that the link can be fixed for the next users.

How to Handle 404s If You Have a Web Site

Here are some things you can do:

- Use a Web site analysis tool such as Web Trends or Weblog to identify links that result in 404s, then fix the links.
- If you change the Uniform Resource Locator (**URL**) for a page on your site, retain the old URL as a redirect file, putting a message on it and inserting a META element with a REFRESH to change to the new URL in a specified number of seconds.

- You can create the page contents for a 404 status code page and substitute it for the 404 page that the browser usually provides. This will allow you to personalize the message and encourage the user to send a note to the Webmaster so that the situation can be fixed.

4G

4G is the short term for fourth-generation **wireless**, the stage of **broadband** mobile communications that will follow the still-burgeoning third generation (3G) that is expected to reach maturity between 2003-2005. 4G services are expected to be introduced first in Japan, as early as 2006—four years ahead of the previous target date. The major distinction of 4G over 3G communications is increased data transmission rates, just as it is for 3G over 2G and 2.5G (the present state of wireless services, hovering somewhere between 2G and 3G). According to NTT-DoCoMo, the leading Japanese wireless company, the current download speed for **i-mode** (mobile internet service) data is—theoretically—9.6 **Kbps**, although in practice the rates tend to be slower. 3G rates are expected to reach speeds 200 times that, and 4G to yield further increases, reaching 20-40 **Mbps** (about 10-20 times the current rates of **ADSL** service).

4G is expected to deliver more advanced versions of the same improvements promised by 3G, such as enhanced **multimedia**, smooth **streaming video**, universal access, and portability across all types of devices. Industry insiders are reluctant to predict the direction that less-than-immediate future technology might take, but 4G enhancements are expected to include worldwide **roaming** capability. As was projected for the ultimate 3G system, 4G might actually connect the entire globe and be operable from any location on—or above—the surface of the earth.

See “programming language generations”

64-bit processor

A 64-bit processor is a **microprocessor** with a **word** size of 64 bits, a requirement for memory and data intensive applications such as computer-aided design (**CAD**) applications, database management systems, technical and scientific applications, and high-performance servers. 64-bit computer **architecture** provides higher performance than 32-bit architecture by handling twice as many bits of information in the same **clock cycle**.

The 64-bit processor is backwards compatible with older applications and operating systems; it detects whether an application or operating system is 16-bit, 32-bit, or 64-bit and computes accordingly. This is essential for enterprise situations where purchasing new software is not feasible.

Intel, IBM, Sun Microsystems, Hewlett Packard, and AMD currently develop or offer 64-bit processors.

80

If you occasionally see a mysterious “80” on the name of a Web **server** that is handling your request for Web pages, this is a bit of technical stuff showing through when perhaps it shouldn't. A Web server sits and waits for requests from a **client** (such as your Web browser). Most Web servers are set up to “awaken” and respond to requests from clients whose Uniform Resource Locator (**URL**) requests include “**port 80**” as part of their information. When you see the “80” showing up in the server address at the bottom of your screen, all it means is that the server uses the usual default port number. (You don't usually see this because some servers can be set up so that this number is not visible to the browser user.)

802.11

In **wireless LAN** (WLAN) technology, 802.11 refers to a family of specifications developed by a working group of the Institute of Electrical and Electronics Engineers (**IEEE**). There are three specifications in the family: 802.11, 802.11a, and 802.11b. All three specify the use of CSMA/CA (carrier sense multiple access with collision avoidance) as the path-sharing protocol.

The 802.11 and 802.11b specifications apply to wireless **Ethernet** LANs, and operate at frequencies in the 2.4-GHz region of the radio spectrum. Data speeds are generally 1 **Mbps** or 2 Mbps for 802.11, and 5.5 Mbps or 11 Mbps for 802.11b, although speeds up to about 20 Mbps are realizable with 802.11b. The 802.11b standard is **backward compatible** with 802.11. The **modulation** used in 802.11 has historically been phase-shift keying (**PSK**). The modulation method selected for 802.11b is known as complementary code keying (**CCK**), which allows higher data speeds and is less susceptible to multipath-propagation interference.

The 802.11a specification applies to wireless **ATM** systems and operates at radio frequencies between 5 **GHz** and 6 GHz. A modulation scheme known as **OFDM** (orthogonal frequency-division multiplexing) makes possible data speeds as high as 54 Mbps, but most commonly, communications take place at 6 Mbps, 12 Mbps, or 24 Mbps.

Also see **HiperLAN**.

802.3

802.3 is a standard specification for **Ethernet**, a method of physical communication in a local area network (**LAN**), which is maintained by the Institute of Electrical and Electronics Engineers (**IEEE**). In general, 802.3 specifies the physical media and the working characteristics of Ethernet. The original Ethernet supports a data rate of 10 megabits per second (**Mbps**) and specifies these possible physical media:

- 10BASE-2 (**Thinwire coaxial cable** with a maximum segment length of 185 meters)
- 10BASE-5 (**Thickwire coaxial cable** with a maximum segment length of 500 meters)
- 10BASE-F (**optical fiber cable**)
- 10BASE-T (ordinary telephone **twisted pair wire**)
- 10BASE-36 (broadband multi-channel coaxial cable with a maximum segment length of 3,600 meters)

This designation is an IEEE shorthand identifier. The “10” in the media type designation refers to the transmission speed of 10 Mbps. The “BASE” refers to baseband signalling, which means that only Ethernet signals are carried on the medium (or, with 10BASE-36, on a single channel). The “T” represents twisted-pair; the “F” represents fiber optic cable; and the “2”, “5”, and “36” refer to the coaxial cable segment length (the 185 meter length has been rounded up to “2” for 200).

Also see **100BASE-T** and **Gigabit Ethernet**.

8-VSB

8-VSB (8-level **vestigial sideband**) is a standard radio frequency (**RF modulation**) format chosen by the Advanced Television Systems Committee (**ATSC**) for the transmission of digital television (**DTV**) to consumers in the United States and other adopting countries. In the US, the standard is specified by the Federal Communications Commission (**FCC**) for all digital television broadcasting. Countries in Europe and elsewhere have adopted an alternative format called Coded Orthogonal Frequency Division Multiplexing (**COFDM**).

The main ATSC standards for DTV are 8-VSB, which is used in the transmission of video data, MPEG-2 for video signal compression, and **Dolby Digital** for audio coding.

The 8-VSB mode includes eight amplitude levels that support up to 19.28 Mbps of data in a single 6 Mhz **channel**. There is also a 16-VSB mode that has 16 amplitude levels and

supports up to 38.57 Mbps of data on a 6 Mhz channel. 8-VSB is considered effective for the simultaneous transmission of more than one DTV program (multicasting) and the transmission of data along with a television program (datacasting) because it supports large data payloads.

The ATSC adopted the VSB transmission system because of its large **bandwidth**, which is needed to transmit **HDTV** (high definition television) programming. Detractors claim that this larger bandwidth is irrelevant if customers cannot view the transmitted program because of multipath effects. When a signal is transmitted, it is met with obstructions such as canyons, buildings, and even people, which scatter the signal, causing it to take two or more paths to reach its final destination, the television set. The late arrival of the scattered portions of the signal causes ghost images. For this reason, some consumers in metropolitan areas or areas with rugged terrain opt for cable television instead of fighting their antennas for better reception. Because a VSB signal is transmitted on one carrier, it scatters like water blasted on a wall when met with obstacles, which is not a problem with Coded Orthogonal Frequency Division Multiplexing (**COFDM**), the European standard modulation technique, because it transmits a signal on multiple carriers.

VSB advocates state that simply buying an outdoor antenna that rotates solves the multipath interference problem, but critics worry that customers do not want to buy an expensive rotating outdoor antenna to view free television programs. They also worry that the poor reception and the added expense of an outdoor antenna are slowing the transition to DTV in ATSC-compliant countries. The VSB scheme also does not support mobile television viewing. VSB equipment manufacturers are working on solutions to these two problems.

A Programming Language

See “APL”

A+

A-Plus (A+) is the name of a process, developed by the Computing Technology Industry Association (CompTIA), a large trade group, that certifies individuals for knowledge about and competency in installing, maintaining, customizing, and operating personal computers. The examination is in two parts, the first covering computer hardware and software in general and the second covering a specific operating system, such as Windows 98. The exam is administered by Drake Parametric and there is a fee. A number of companies provide in-house or self-taught preparation for the exam.

CompTIA also sponsors specialized certification for document imaging and a network certification exam. The A-Plus certification is somewhat more basic and less product-specific than other certifications, such as Microsoft’s **Microsoft Certified Systems Engineer** certifications.

An advantage of certification in any industry is that it promotes self-regulation rather than government regulation.

a2b

a2b (for short; the site is actually called “a2b music”) is a Web site that lets you **download** and play samples or complete songs from popular music recordings, using a music player developed by AT&T. At the a2b music Web site, after first downloading the player, you can then download and play short samples or complete songs from new CD music recordings. The sound, which is said to be “CD-quality,” is made possible through **MPEG** standard Advanced Audio Coding (AAC), a technology that AT&T Labs helped to develop. After sampling a short preview of a song, you can download the entire song from the Web site. Some songs are free and some require an online purchase. You are also invited to purchase the entire CD from the site using secure online ordering. a2b music partners include major recording companies and new releases include those from such artists as Tori Amos, Counting Crows, Willie Nelson, and Bonnie Raitt.

The **compression algorithm** uses a successor to the MP3 (MPEG-1, layer 3) technology that a2b says offers better stereo sound and such advances as *temporal noise shaping* and *pairwise coding*. a2b uses public key cryptography to ensure that only the purchaser can play the music. The player is initially offered for Windows 9x/NT users and is promised for Mac users.

AA

See “modem lights”

AAA server

An AAA server is a **server** program that handles user requests for **access** to computer resources and, for an enterprise, provides **authentication**, **authorization**, and **accounting** (AAA) services. The AAA server typically interacts with network access and **gateway** servers and with databases and directories containing user information. The current standard by which devices or applications communicate with an AAA server is the Remote Authentication Dial-In User Service (**RADIUS**).

Also see **authentication, authorization, and accounting**.

AARP

AARP (AppleTalk Address Resolution Protocol) is a way to map between the physical hardware addresses of computers, such as those known to an **Ethernet** or **token ring** local area network, and their temporarily assigned **AppleTalk** network addresses.

AAUI

An AAUI (Apple **attachment unit interface**) is the 14- or 15-**pin** port or connection interface on earlier models of **Macintosh** computers that allowed it to be connected by a short interface cable (or “transceiver”) to an **Ethernet** cable. Later or more advanced models provide a standard registered jack (10Base-T) connection from an Ethernet-capable Macintosh to the Ethernet cable.

abacus

An abacus is a manual aid to calculating that consists of beads or disks that can be moved up and down on a series of sticks or strings within a usually wooden frame. The abacus itself doesn’t calculate; it’s simply a device for helping a human being to calculate by remembering what has been counted. The modern Chinese abacus, which is still widely used in China and other countries, dates from about 1200 A.D. It is possible that it derives from the earlier **counting boards** used around the Mediterranean as early as 300 B.C. An Aztec version of an abacus, circa 900-1000 A.D., is made from maize (corn) threaded through strings mounted in a wooden frame.

There are Japanese and Russian versions of the abacus and several modern “improved” versions.

abampere

The abampere (symbolized abA) is the unit of **current** in the **cgs** (centimeter/gram/second) system of electromagnetic units. It is the equivalent of one **abcoulomb** (1 abC) of charge carriers moving past a specific point in one second.

The abampere is a moderately large unit of current, equivalent to 10 **amperes** (A). In most applications, the ampere, which is the unit of current in the International System of Units (SI), is preferred.

Also see **current**, **cgs** or **small-unit metric system**, and International System of Units (SI).

abandonware

Abandonware is computer software (such as an **operating system**, word processor, interactive game, or audio file) that is no longer marketed or distributed by the company that created it, but is obtainable from some other source. Some popular products that have been at least temporarily abandoned include NeXTStep, the operating system for the NEXT computer; OpenStep, its successor; and many interactive games that were replaced by more sophisticated products. In some cases, a company or Web site gets permission from the creator to distribute the abandoned program; but sometimes they don't. To use abandonware that you download, you often need a *license string* that the software recognizes as entitling the user to install it. In this case, the downloading site provides a license string that is known to work.

Abandonware is often provided as **freeware** or as priced **shareware**.

ABAP

ABAP is a programming language for developing applications for the SAP R/3 system, a widely-installed business application subsystem. The latest version, ABAP Objects, is **object-oriented programming**. SAP will run applications written using ABAP/4, the earlier ABAP version, as well as applications using ABAP Objects.

SAP's original business model for R/3 was developed before the idea of an object-oriented model was widespread. The transition to the object-oriented model reflects an increased customer demand for it. ABAP Objects uses a single **inheritance** model and full support for object features such as **encapsulation**, **polymorphism**, and persistence.

ABBH

See "average bouncing busy hour"

ABCD data switch

An ABCD data switch is a small box that lets you hook up to four devices from one PC serial or parallel **port** on your computer. For example, if you have both a black-and-white

laser printer for regular printing and a color inkjet printer for when you want color, you may want to attach them both to your computer. Perhaps you also have a tape backup drive that needs to be attached. You can connect all of them to the ABCD box which is in turn connected to your PC's parallel port. By turning a rotary switch on the box to the A, B, C, or D (if you have a fourth device attached) position, you can select the device you want to be active. (You will need to tell your operating system the kind of device that's attached whenever you switch.)

The data switch can also be used to have up to four computers share the same printer or other device.

This handy little switch costs about \$20 (U.S.) and can be purchased in local PC stores.

abcoulomb

The abcoulomb (abbreviated abC) is the unit of **charge quantity** in the **cgs** (centimeter/gram/second) system of electromagnetic units. It is approximately equal to the charge contained in 6.24×10^{19} **electrons**.

The force with which two electrically charged bodies attract or repel one another depends on the product of the charges in abcoulombs in both objects, and also on the distance between the objects. If the polarities are the same, the force is repulsive; if the polarities are opposite, the force is attractive. For any two charged bodies, the force decreases in proportion to the square of the distance between their charge centers.

The abcoulomb is a moderately large unit in practical terms, equivalent to 10 coulombs (C). In most applications, the **coulomb**, which is the standard unit of charge quantity in the International System of Units (SI), is preferred.

Also see **charge quantity**, **cgs** or **small-unit metric system**, and International System of Units (SI).

abend

An abend (a combining of two words, *abnormal end*, when operator messages were as short as possible) is an abnormal, rather than planned, end or termination of a computer program because of some problem with how it is running. For example, the program may have attempted to address some computer memory space that it was not given the right to address. This term is more common in older **mainframe** systems than in PC systems.

When used, abend usually refers to the abnormal end of an application program because of application errors. Failure of the operating system is usually called a **crash**. In smaller systems, the term crash is applied to both application program and operating system failure. A crash also can be caused by hardware failure.

abfarad

The abfarad (abbreviated abF) is the unit of electromagnetic **capacitance** in the **cgs** (centimeter/gram/second) system of units. If a charge of one **abcoulomb** (1 abC) produces a potential difference of one **abvolt** (1 abV) in a capacitance, then that capacitance is 1 abF.

A capacitance as large as 1 abF is unknown. It is equivalent to 10^9 farads. The **farad** (F) is the standard unit of capacitance in the International System of Units (SI). Even this unit is large; a 1-F capacitor is almost never found in the real world.

In practical applications, the microfarad (μF) and the picofarad (pF) are most often used to quantify capacitance; the abfarad is rarely seen in literature. For comparison, $1 \mu\text{F} = 10^{-6} \text{ F}$ and $1 \text{ pF} = 10^{-12} \text{ F}$. Thus, $1 \text{ abF} = 10^{15} \mu\text{F} = 10^{21} \text{ pF}$.

Also see **capacitance**, **farad**, **cgs** or **small-unit metric system**, and International System of Units (SI).

abhenry

The abhenry (abbreviated abH) is the unit of electromagnetic **inductance** in the **cgs** (centimeter/gram/second) system of units. It is equivalent to 10^{-9} **henry**. In a 1-abH inductance, a **current** that increases or decreases at one **abampere** per second (1 abA/s) will produce an electromotive force (EMF) of one **abvolt** (1 abV).

It is unusual to see an inductance as large as one henry (1 H) in the real world, but a 1-abH inductance is small, and is not uncommon. In fact, 1 abH is the equivalent of one nanohenry (1 nH), an often-used unit of inductance, especially at ultra-high and microwave radio frequencies. The henry is the standard unit of inductance in the International System of Units (SI).

In practical applications, the microhenry (μH) and the nanohenry (nH) are most often used to quantify inductance. For comparison, $1 \mu\text{H} = 10^{-6} \text{ H}$ and $1 \text{ nH} = 10^{-9} \text{ H}$. Thus, $1 \text{ abH} = 0.001 \mu\text{H} = 1 \text{ nH}$.

Also see **inductance**, **henry**, **cgs** or **small-unit metric system**, and International System of Units (SI).

abohm

The abohm (symbolized ab Ω) is the unit of electromagnetic **resistance** in the **cgs** (centimeter/gram/second) system of units. It is equivalent to 10^{-9} **ohms**. When a current of one **abampere** (1 abA) flows through a resistance of 1 ab Ω , the resulting potential difference across the component is one **abvolt** (1 abV).

The abohm is an extremely small unit of resistance. In fact, an object with a resistance of 1 ab Ω would make an excellent electrical **conductor**. In practical applications, the ohm, the kilohm (k Ω) and the megohm (M Ω or M) are most often used

to quantify resistance. For comparison, $1 \text{ ab}\Omega = 10^{-15} \text{ M}\Omega = 10^{-12} \text{ k}\Omega$. The ohm (Ω) is the standard unit of resistance in the International System of Units (SI).

Also see **resistance**, **ohm**, **cgs** or **small-unit metric system**, and International System of Units (SI).

absiemens

The absiemens (symbolized abS) is the unit of **conductance** in the **cgs** (centimeter/gram/second) electromagnetic system of units. It is equivalent to 10^9 siemens (S).

When a **current** of one **abampere** (1 abA) flows through a conductance of 1 abS, the resulting potential difference across the component is one **abvolt** (1 abV). If the conductance is doubled while the current remains the same, the resulting voltage across the component is cut in half. Conversely, if the conductance is cut in half while the current remains the same, the resulting voltage across the component is doubled. The conductance in absiemens is the reciprocal of the resistance in **abohms** (ab Ω).

The absiemens is an extremely large unit of conductance. In fact, an object with a conductance of 1 abS would make an excellent electrical conductor. In practical applications, the siemens, the millisiemens (mS) and the microsiemens (μS) are most often used to quantify conductance. For comparison, $1 \text{ abS} = 10^{15} \mu\text{S} = 10^{12} \text{ mS}$. The siemens is the standard unit of conductance in the International System of Units (SI).

Also see **abohm**, **conductance**, **siemens**, **cgs** or **small-unit metric system**, and International System of Units (SI).

Abstract Syntax Notation One

Abstract Syntax Notation One (ASN.1) is a standard way to describe a **message** (a unit of **application data**) that can be sent or received in a network. ASN.1 is divided into two parts: (1) the rules of **syntax** for describing the contents of a message in terms of **data type** and content sequence or structure and (2) how you actually encode each data item in a message. ASN.1 is defined in two **ISO** standards for applications intended for the Open Systems Interconnection (OSI) framework:

- ISO 8824/ITU X.208 specifies the syntax (for example, which data item comes first in the message and what its data type is)
- ISO 8825/ITU X.209 specifies the basic encoding rules for ASN.1 (for example, how to state how long a data item is)

Here's an example of a message definition specified with ASN.1 notation:

```
Report ::= SEQUENCE {
    author    OCTET STRING,
    title     OCTET STRING,
    body      OCTET STRING,
    biblio    Bibliography }
```

In this very simple example, “Report” is the name of this type of message. SEQUENCE indicates that the message is a sequence of data items. The first four data items have the data type of OCTET STRING, meaning each is a string of eight-bit **byte** (the term OCTET was used rather than BYTE because it can’t be assumed that all computers will have eight bits in a byte). The bibliography data item is another definition named “Bibliography” that is used within this one. It might look like this:

```
Bibliography ::= SEQUENCE {
    author    OCTET STRING
    title     OCTET STRING
    publisher OCTET STRING
    year     OCTET STRING
}
```

Other data types that can be specified include: INTEGER, BOOLEAN, REAL, and BIT STRING. An ENUMERATED data type is one that takes one of several possible values. Data items can be specified as OPTIONAL (not necessarily present).

Abstract Window Toolkit

Abstract Window Toolkit (AWT) is a set of application program interfaces (APIs) used by **Java** programmers to create graphical user interface (GUI) objects, such as buttons, scroll bars, and windows. AWT is part of the Java Foundation Classes (JFC) from Sun Microsystems, the company that originated Java. The JFC are a comprehensive set of GUI **class** libraries that make it easier to develop the user interface part of an application program.

A more recent set of GUI interfaces called **Swing** extends the AWT so that the programmer can create generalized GUI objects that are independent of a specific operating system’s **windowing system**.

abstraction

Abstraction (from the Latin *abs*, meaning *away from* and *trahere*, meaning *to draw*) is the process of taking away or removing characteristics from something in order to reduce it to a set of essential characteristics. In **object-oriented programming**, abstraction is one of three central principles (along with **encapsulation** and **inheritance**). Through the process of abstraction, a programmer hides all but the relevant data about an **object** in order to reduce complexity and increase efficiency. In the same way that abstraction sometimes works in art, the object that remains is a representation of the original, with unwanted detail omitted. The resulting object itself can be referred to as an abstraction, meaning *a named entity made up of selected attributes and behavior specific to a particular usage of the originating entity*. Abstraction is related to both **encapsulation** and **data hiding**.

In the process of abstraction, the programmer tries to ensure that the **entity** is named in a manner that will make sense and that it will have all the relevant aspects included and

none of the extraneous ones. A real-world analogy of abstraction might work like this: You (the object) are arranging to meet a blind date and are deciding what to tell them so that they can recognize you in the restaurant. You decide to include the information about where you will be located, your height, hair color, and the color of your jacket. This is all data that will help the procedure (your date finding you) work smoothly. You should include all that information. On the other hand, there are a lot of bits of information about you that aren’t relevant to this situation: your social security number, your admiration for obscure films, and what you took to “show and tell” in fifth grade are all irrelevant to this particular situation because they won’t help your date find you. However, since entities may have any number of abstractions, you may get to use them in another procedure in the future.

abvolt

The abvolt (symbolized abV) is the unit of electromotive force (EMF) or potential difference in the **cgs** (centimeter/gram/second) electromagnetic system of units. When an EMF of 1 abV exists between two points, then one **erg** of energy is needed to move one **abcoulomb** (1 abC) of charge carriers between those two points.

A potential difference of 1 abV will drive a current of one **abampere** (1 abA) through a resistance of one abohm (abΩ). **Ohm’s Law** applies for the cgs electromagnetic units, just as it does for the units in the International System of Units (SI). That is:

$$E = IR$$

where E is the EMF in abvolts, I is the **current** in abamperes, and R is the **resistance** in abohms.

The abvolt is a tiny unit of EMF, equal to 10^{-8} volts (V). In most practical applications, the **volt**, which is the unit of potential difference in SI, is preferred.

Also see **voltage**, **cgs** or **small-unit metric system**, and International Systems of Units (SI).

abwatt

The abwatt (symbolized abW) is the unit of power in the **cgs** (centimeter/gram/second) electromagnetic system of units. In a direct-current (DC) circuit, 1 abW is the **power** dissipated, radiated, or expended when one **abvolt** (1 abV) of potential difference drives a **current** of one **abampere** (1 abA) through a component.

In a DC circuit, or in an alternating-current (AC) circuit in which there is no **reactance**, the following formula holds:

$$P = EI$$

where P is the power in abwatts, E is the potential difference in abvolts, and I is the current in **abamperes**.

The abwatt is a small unit of power, equivalent to 10^{-7} watt (W) or 0.1 microwatt (μ W). The abwatt, by coincidence, is the same size as the **statwatt** (statW), the unit of power in the cgs

electrostatic system of units. But in most applications, the watt, which is the unit of power in the International System of Units (SI), is preferred.

Also see **power**, **watt**, **cgs** or **small-unit metric system**, and International System of Units (SI).

AC

See "alternating current"

Accelerated Graphics Port

AGP (Accelerated Graphics Port) is an **interface** specification that enables 3-D graphics to display quickly on ordinary personal computers. AGP is an interface designed to convey 3-D images (for example, from Web sites or CD-ROMs) much more quickly and smoothly than is possible today on any computer other than an expensive graphics workstation. The interface uses your computer's main storage (**RAM**) for refreshing the monitor image and to support the *texture mapping*, *z-buffering*, and *alpha blending* required for 3-D image display. The AGP main memory use is dynamic, meaning that when not being used for accelerated graphics, main memory is restored for use by the **operating system** or other applications.

Intel, which has taken the lead in developing its specifications, introduced AGP into a **chipset** for its **Pentium microprocessor**. The newer, faster microchips in Intel's Pentium line are designed to work with the AGP chipset. Intel says the advanced **floating point unit** and faster **cache** algorithm of the more advanced Pentiums are better adapted for 3-dimensional applications.

Accelerated Hub Architecture

Accelerated Hub Architecture (AHA) (also called Intel Hub Architecture) is an Intel 800-series **chipset** design that uses a dedicated **bus** to transfer data between the two main **processor** chips instead of using the Peripheral Component Interconnect (**PCI**) bus, which was used in previous chipset architectures. The Accelerated Hub Architecture provides twice the **bandwidth** of the traditional PCI bus architecture at 266 **MB** per second. The Accelerated Hub Architecture consists of a **memory controller hub** and an input/output (**I/O**) controller hub (a controller directs or manages access to devices). The memory controller hub provides the central processing unit (**CPU**) **interface**, the memory interface, and the accelerated graphics port (**AGP**) interface. The memory controller hub supports single or dual processors with up to 1 **GB** of memory. The memory controller hub also allows for simultaneous processing, which enables more life-like audio and video capabilities.

The I/O controller hub provides a direct connection from the memory to the I/O devices, which includes any built-in modem and audio controllers, hard drives, Universal Serial Bus (**USB**) ports, and PCI add-in cards. The I/O controller

hub also includes the Alert on LAN (**local area network**) feature that sounds an alert when software failures or system intrusion occurs.

acceptable use policy

An acceptable use policy (AUP) is a policy that a network access user must agree to follow in order to be provided with access service. When you sign up with an Internet service provider (**ISP**), you will usually be presented with an AUP, which states that you agree to adhere to stipulations such as:

- Not using the service as part of violating any law
- Not attempting to break the security of any computer network or user
- Not posting commercial messages to **Usenet** groups without prior permission
- Not attempting to send junk e-mail or **spam** to anyone who doesn't want to receive it
- Not attempting to **mail bomb** a site with mass amounts of e-mail in order to flood their server.

Users also typically agree to report any attempt to break into their accounts. A number of spammers have had their access service terminated.

access

Access is simply being able to get to what you need. Data access is being able to get to (usually having permission to use) particular data on a computer. Web access means having a connection to the World Wide Web through an **access provider** or an **online service provider** such as America Online.

For data access, access is usually specified as read-only access and read/write access.

access control list

An access control list (ACL) is a table that tells a computer **operating system** which **access** rights each user has to a particular system object, such as a file **directory** or individual **file**. Each object has a security attribute that identifies its access control list. The list has an entry for each system user with access privileges. The most common privileges include the ability to read a file (or all the files in a directory), to write to the file or files, and to execute the file (if it is an executable file, or program). Microsoft **Windows NT/2000**, Novell's **NetWare**, Digital's **OpenVMS**, and **UNIX**-based systems are among the operating systems that use access control lists. The list is implemented differently by each operating system.

In Windows NT/2000, an access control list (ACL) is associated with each system object. Each ACL has one or more access control entries (ACEs) consisting of the name of a user or group of users. The user can also be a role name,

such as “programmer,” or “tester.” For each of these users, groups, or roles, the access privileges are stated in a string of bits called an *access mask*. Generally, the system administrator or the object owner creates the access control list for an object.

access log

An access log is a list of all the requests for individual files that people have requested from a Web site. These files will include the **HTML** files and their imbedded graphic images and any other associated files that get transmitted. The access log (sometimes referred to as the “raw data”) can be analyzed and summarized by another program.

In general, an access log can be analyzed to tell you:

- The number of visitors (unique first-time requests) to a **home page**
- The origin of the visitors in terms of their associated server’s **domain name** (for example, visitors from .edu, .com, and .gov sites and from the online services)
- How many requests for each page at the site, which can be presented with the pages with most requests listed first
- Usage patterns in terms of time of day, day of week, and seasonally

Access log keepers and analyzers can be found as **shareware** on the Web or may come with a Web **server**.

access method

1) In computing, an access method is a program or a hardware mechanism that moves data between the computer and an outlying device such as a **hard disk** (or other form of **storage**) or a display terminal. The term is sometimes used to refer to the mechanics of placing or locating specific data at a particular place on a storage medium and then writing the data or reading it. It is also used to describe the way that data is located within a larger unit of data such as a **data set** or **file**.

2) An access method is also an application program interface (**API**) that a programmer uses to create or access data sets or to read from or write to a display terminal or other output device. Examples are the Virtual Sequential Access Method (**VSAM**) and the Virtual Telecommunication Access Method (**VTAM**).

access provider

An access provider is any organization that arranges for an individual or an organization to have access to the Internet. Access providers are generally divided into two classes: Internet access providers (**ISPs**) and online service providers (**OSPs**). ISPs can be local businesses that pay for a high-speed connection to one of the companies (such as AT&T, Sprint, or MCI in the U.S.) that are part of the Internet. They can also be national or international companies that have

their own networks (such as AT&T’s WorldNet or IBM’s Global Services). OSPs, sometimes just called “online services,” also have their own networks but provide additional information services not available to non-subscribers. America Online is the most successful example of an OSP.

A typical charge from an access provider for an individual account is \$10–30 U.S. a month, depending on the amount of usage you contract for. Hours of use beyond the arranged number are billed as an extra charge at an hourly rate. Both national and local access providers compete for business in national and local publications.

Microsoft’s Windows systems offer personal computer users access to the Microsoft Internet service as well as to America Online, IBM, and several other services.

An access provider may have its own point-of-presence (**POP**) on the Internet, or it may be a company that has a telecommunication connection to someone else with a POP.

An access provider is not the same as a “space provider” (**virtual host**), a company that provides space and management for individual or business Web sites. However, some access providers do provide a certain amount of space for a Web site as part of their service.

access time

Access time is the time from the start of one storage device access to the time when the next access can be started. Access time consists of **latency** (the overhead of getting to the right place on the device and preparing to access it) and transfer time.

The term is applied to both random access memory (**RAM**) access and to **hard disk** and **CD-ROM** access. For RAM access, IBM prefers the term **cycle time**. However, the use of *access time* for RAM access is common. Access time to RAM is usually measured in **nanoseconds**. Access time to a hard disk or CD-ROM is usually measured in **milliseconds**.

ACD

See “Automatic Call Distributor”

ACH

See “Automated Clearing House”

ACID

ACID (atomicity, consistency, isolation, and durability) is an acronym and **mnemonic** device for learning and remembering the four primary attributes ensured to any transaction by a **transaction manager** (which is also called a transaction monitor). These attributes are:

Atomicity. In a transaction involving two or more discrete pieces of information, either all of the pieces are committed or none are.

#

A

B

C

D

E

F

G

H

I

J

K

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

Consistency. A transaction either creates a new and valid state of data, or, if any failure occurs, returns all data to its state before the transaction was started.

Isolation. A transaction in process and not yet committed must remain isolated from any other transaction.

Durability. Committed data is saved by the system such that, even in the event of a failure and system restart, the data is available in its correct state.

The ACID concept is described in ISO/IEC 10026-1:1992 Section 4. Each of these attributes can be measured against a **benchmark**. In general, however, a transaction manager or monitor is designed to realize the ACID concept. In a **distributed** system, one way to achieve ACID is to use a (2PC), which ensures that all involved sites must commit to transaction completion or none do, and the transaction is **rollback**.

ACL

See "access control list"

ACM

See "Association for Computing Machinery"

acoustic coupler

An acoustic coupler is a hardware device that enables a **modem** (a device that converts signals from **analog** to **digital** and from digital back to analog) to connect to a voice circuit. A handset adapter is used to receive modem tones through the handset's mouthpiece, and the earpiece is used to transmit these tones to the modem.

Acrobat

Acrobat is a program from Adobe that lets you capture a document and then view it in its original format and appearance. Acrobat is ideal for making documents or brochures that were designed for the print medium viewable electronically and capable of being shared with others on the Internet. To view an Acrobat document, which is called a Portable Document Format (**PDF**) file, you need Acrobat Reader. The Reader is free and can be downloaded from Adobe. You can use it as a standalone reader or as a **plug-in** in a Web browser.

Acrobat is actually a set of products. The latest version includes a "toolkit" that lets you scan in or otherwise capture documents created with Word, Pagemaker, and other desktop publishing products. The resulting PDF files can then be available for viewing either directly with the Reader or they can be viewed as embedded files within the browser.

acronym

An acronym (pronounced AK-ruh-nihm, from Greek *acro-* in the sense of *extreme* or *tip* and *onyma* or *name*) is an abbreviation of several words in such a way that the abbreviation itself forms a word. According to Webster's, the word doesn't have to already exist; it can be a new word. Webster's cites "snafu" and "radar", two terms of World War Two vintage, as examples. Implicit is the idea that the new word has to be pronounceable and ideally easy to remember.

Frequently, acronyms are formed that use existing words (and sometimes the acronym is invented first and the phrase name represented is designed to fit the acronym). Here are some examples of acronyms that use existing words:

BASIC....Beginner's All-Purpose Symbolic Instruction Code
NOW.....National Organization for Women
WHO.....World Health Organization

Abbreviations that use the first letter of each word in a phrase are sometimes referred to as initialisms. Initialisms can be but are not always acronyms. AT&T, BT, CBS, CNN, IBM, and NBC are initialisms that are not acronyms. Many acronym lists you'll see are really lists of acronyms and initialisms or just lists of abbreviations. (Note that abbreviations include shortened words like "esp" for "especially" as well as shortened phrases.)

Summing up:

- An abbreviation is a shortening of a word or a phrase.
- An acronym is an abbreviation that forms a word.
- An initialism is an abbreviation that uses the first letter of each word in the phrase (thus, some but not all initialisms are acronyms).

By the way, an acronym so familiar that no one remembers what it stands for is called an **anacronym**.

acronyms used in online chatting

See "chat abbreviations"

ACTA

ACTA (America's Carriers Telecommunications Association) is a lobbying organization for over 165 small long-distance telephone **carrier** companies. It was organized in 1985 to represent the interests of the group before legislative and regulatory bodies. The organization is based in Casselberry, Florida.

Active Directory

Active Directory is Microsoft's trademarked **directory** service, an integral part of the **Windows 2000** architecture. Like other directory services, such as Novell Directory Services (**NDS**), Active Directory is a centralized and standardized system that automates network management

of user data, security, and **distributed** resources, and enables interoperation with other directories. Active Directory is designed especially for distributed networking environments.

Active Directory features include:

- Support for the **X.500** standard for global directories
- The capability for secure extension of network operations to the Web
- A hierarchical organization that provides a single point of access for system administration (management of user accounts, clients, servers, and applications, for example) to reduce redundancy and errors
- An object-oriented storage organization, which allows easier access to information
- Support for the Lightweight Directory Access Protocol (LDAP) to enable inter-directory operability
- Designed to be both **backward compatible** and **forward compatible**

active matrix display

Active matrix (also known as **thin film transistor**) is a technology used in the flat panel liquid crystal displays of notebook and laptop computers. Active matrix displays provide a more responsive image at a wider range of viewing angle than *dual scan* (passive matrix) displays.

Desktop computer displays or monitors usually have *cathode ray tube* technology.

active network

An active network is a **network** in which the **nodes** are programmed to perform custom operations on the messages that pass through the node. For example, a node could be programmed or customized to handle **packets** on an individual user basis or to handle **multicast** packets differently than other packets. Active network approaches are expected to be especially important in networks of mobile users. "Smart packets" use a special self-describing language that allows new kinds of information to be carried within a packet and operated on by a node.

A Secure Active Network Environment (SANE) is an architecture for a trusted or secure active network.

Active Server Page

ASP is also an abbreviation for **application service provider**.

An Active Server Page (ASP) is an **HTML** page that includes one or more **scripts** (small embedded programs) that are processed on a Microsoft Web **server** before the **page** is sent to the user. An ASP is somewhat similar to a **server-side include** or a common gateway interface (CGI) application in that all involve programs that run on the server, usually tailoring a page for the user. Typically, the script in the Web page at the server uses input received as the result of the

user's request for the page to access data from a **database** and then builds or customizes the page **on the fly** before sending it to the requestor.

ASP is a feature of the Microsoft Internet Information Server (IIS), but, since the server-side script is just building a regular HTML page, it can be delivered to almost any **browser**. You can create an ASP file by including a script written in **VBScript** or **JScript** in an HTML file or by using ActiveX Data Objects (ADOs) program statements in the HTML file. You name the HTML file with the ".asp" file suffix. Microsoft recommends the use of the server-side ASP rather than a client-side script, where there is actually a choice, because the server-side script will result in an easily displayable HTML page. Client-side scripts (for example, with **JavaScript**) may not work as intended on older browsers.

Active Template Library

Active Template Library (ATL), formerly called ActiveX Template Library) is a Microsoft program library (set of prepackaged program routines) for use when creating Active Server Page (ASP) code and other **ActiveX** program **components** with **C++** (including Visual C++). A Web site developer that wants to forward user requests to a program in the Web **server** can write a **common gateway interface** application or, if the server is Microsoft's Internet Information Server (IIS), can include a **script** in the **HTML** (Web) page. The page itself is called an Active Server Page (ASP) and has a suffix of .asp. The script in the Active Server Page is interpreted and performed at the server before the page is sent on to the user. Another approach is to have this script (written in Microsoft's VBScript or JScript) in turn call a compiled program, written typically in C++, a sophisticated **object-oriented programming** language. Since a compiled program runs faster than a script, the Web page will be formulated faster and returned more quickly to the user. A C++ program also can interface more closely with the **operating system** than a script can, and there are several other advantages. On the other hand, it is more difficult and time-consuming to write a program in C++ than to write one in a script language.

The Active Template Library lets the programmer build **Component Object Models** **object** that can be called by the script on an ASP page. These objects are described by Microsoft as being fast and having **industrial strength**. Objects you can build using the ATL include full controls, Internet Explorer controls, property pages, and dialog boxes.

ActiveX

Also see **ActiveX control**.

ActiveX is the name Microsoft has given to a set of "strategic" **object-oriented programming** technologies and tools. The main technology is the **Component Object Model** (COM). Used in a network with a directory and additional

support, COM becomes the **Distributed Component Object Model** (DCOM). The main thing that you create when writing a program to run in the ActiveX environment is a **component**, a self-sufficient program that can be run anywhere in your ActiveX network (currently a network consisting of Windows and Macintosh systems). This component is known as an **ActiveX control**. ActiveX is Microsoft's answer to the **Java** technology from Sun Microsystems. An ActiveX control is roughly equivalent to a **Java applet**.

If you have a Windows operating system on your personal computer, you may notice a number of Windows files with the "**OCX**" file name suffix. OCX stands for "Object Linking and Embedding control." Object Linking and Embedding (OLE) was Microsoft's program technology for supporting **compound documents** such as the Windows **desktop**. The Component Object Model now takes in OLE as part of a larger concept. Microsoft now uses the term "ActiveX control" instead of "OCX" for the component object.

One of the main advantages of a component is that it can be re-used by many applications (referred to as component **containers**). A COM component object (ActiveX control) can be created using one of several languages or development tools, including **C++** and **Visual Basic**, or **PowerBuilder**, or with scripting tools such as **VBScript**.

Currently, ActiveX controls run in Windows 95/98/NT/2000 and in Macintosh. Microsoft plans to support ActiveX controls for UNIX.

ActiveX control

An ActiveX control is a **component program object** that can be re-used by many application programs within a computer or among computers in a network. The technology for creating ActiveX controls is part of Microsoft's overall **ActiveX** set of technologies, chief of which is the **Component Object Model** (COM). ActiveX controls can be downloaded as small programs or animations for Web pages, but they can also be used for any commonly needed task by an application program in the latest Windows and Macintosh environments. In general, ActiveX controls replace the earlier **OCX** (Object Linking and Embedding custom controls). An ActiveX control is roughly equivalent in concept and implementation to the **Java applet**.

An ActiveX control can be created in any programming language that recognizes Microsoft's Component Object Model. The distributed support for COM is called the Distributed Component Object Model (**DCOM**). In implementation, an ActiveX control is a dynamic link library (**DLL**) module. An ActiveX control runs in what is known as a **container**, an application program that uses the Component Object Model program interfaces. This reuseable component approach to application development reduces development time and improves program capability and

quality. Windows application development programs such as **PowerBuilder** and Microsoft Access take advantage of ActiveX controls.

Visual Basic and **C++** are commonly used to write ActiveX controls.

ActiveX Data Objects

ActiveX Data Objects (ADO) is an **application program interface** from Microsoft that lets programmers writing Windows applications get access to a relational or nonrelational **database** from both Microsoft and other database providers. For example, if you wanted to write a program that would provide users of your Web site with data from an IBM **DB2** database or an **Oracle** database, you could include ADO program statements in an **HTML** file that you then identified as an **Active Server Page**. When a user requested the page from the Web site, the page sent back could include appropriate data from a database, obtained using ADO code.

Like Microsoft's other system interfaces, ADO is an **object-oriented programming** interface. It is also part of an overall data access strategy from Microsoft called **Universal Data Access**. Microsoft says that rather than try to build a universal database as IBM and Oracle have suggested, why not provide universal *access* to various kinds of existing and future databases? In order for this to work, Microsoft and other database companies provide a "bridge" program between the database and Microsoft's OLE DB, the low-level interface to databases. OLE DB is the underlying system service that a programmer using ADO is actually using. A feature of ADO, Remote Data Service, supports "data-aware" **ActiveX controls** in Web pages and efficient client-side **caches**. As part of **ActiveX**, ADO is also part of Microsoft's overall **Component Object Model** (COM), its **component-oriented** framework for putting programs together.

ADO evolved from an earlier Microsoft data interface, **Remote Data Objects** (RDO). RDO works with Microsoft's ODBC to access relational databases, but not nonrelational databases such as IBM's **ISAM** and **VSAM**.

ACTS

ACTS (Automatic Coin Telephone System) is a public coin-operated telephone service that completes a variety of phone calls, times the calls, and collects payment without the aid of an operator.

Ada

Ada (pronounced AY-duh) is a programming language somewhat similar to **Pascal** that was selected in a competition and made a U.S. Defense Department standard. (It is named for Augusta Ada Byron, Countess of Lovelace [1815-1852], who helped **Charles Babbage** conceive how programs might run in his mechanical Analytical Engine.

She is often considered the first computer programmer.) Ada was originally intended for real-time **embedded systems programming**.

By its supporters, Ada is described as a programming language that avoids error-prone notation, is relatively quick to implement, encourages reuse and team coordination, and is relatively easy for other programmers to read. The most recent version, Ada 95, is apparently a significant improvement over earlier versions. Among the sophisticated, according to *The New Hacker's Dictionary*, Ada has a reputation as a committee-written language, with poor exception-handling and **interprocess communication** features. It's not clear that "hackers" still feel this way. The Ada home page says: "The original Ada design was the winner of a language design competition; the winning team was headed by Jean Ichbiah (Ichbiah's language was called "Green"). The 1995 revision of Ada (Ada 95) was developed by a small team led by Tucker Taft. In both cases, the design underwent a public comment period where the designers responded to public comments."

Ada 95 can be used with **object-oriented programming** design methodology and source code can be compiled into **Java** classes by the Ada 95 **compiler**. These classes can be run as Java applets or applications on a Java **virtual machine**.

First standardized by **ANSI** in 1983 and **ISO** in 1987, the latest standard is ANSI/ISO/IEC-8652:1995 Ada 95.

adapter

An adapter is a physical device that allows one hardware or electronic interface to be adapted (accommodated without loss of function) to another hardware or electronic interface. In a computer, an adapter is often built into a **card** that can be inserted into a slot on the computer's motherboard. The card adapts information that is exchanged between the computer's microprocessor and the devices that the card supports.

adaptive differential pulse-code modulation

See "ADPCM"

ADAT

The ADAT (a registered trademark of Alesis) is an eight-track digital tape recorder that caught the recording industry by storm when it was first released in the early 1990s. Today, with over 100,000 ADATs in use in recording facilities around the world, it is the most widely used professional digital recording system. The ADAT was the first product in the category now known as modular digital multitracks (MDMs).

The ADAT system allows up to 16 ADAT units to be used in synchronization, enabling the user to build a very cost-effective multi-track recording environment. The transportability and modularity of the system makes it ideal for mobile recording and wherever space is limited.

Digital transfer between ADATs in a system uses a **optical fiber** digital communication standard pioneered by Alesis which has become known as Lightpipe. The Lightpipe digital interface has been adopted by other manufacturers as a means of transferring digital data from other types of audio devices, such as mixers, synthesizers, and effect processors.

The ADAT uses the S-VHS ½ inch tape format. This tape is similar in design to the tape used in consumer VCRs.

ADC

See "analog-to-digital conversion"

add-in

Add-in is a term used, especially by Microsoft, for a software **utility** or other program that can be added to a primary program. The Microsoft Style Guide says that Microsoft Bookshelf is an add-in for Word and that Analysis Toolpak is an add-in for Microsoft Excel. According to the Style Guide, add-in should not be confused with **add-on**, a term for a hardware expansion unit. (However, some add-on manufacturers do call them "add-ins.")

A similar term is **plug-in**, a term originated by Netscape for application programs that can be activated within a Netscape Web **browser** window.

add-on

An add-on is either a hardware unit that can be added to a computer to increase its capabilities or a program **utility** that enhances a primary program. Less frequently, some manufacturers and software developers use the term **add-in**. Examples of add-ons for a computer include **cards** for sound, graphics acceleration, modem capability, and memory. Software add-ons are common for games, word processors, and accounting programs.

The Microsoft Style Guide suggests using add-ons for hardware only and add-ins for software utilities. Industry-wide, however, this guideline does not seem to be widely followed.

A similar term is **plug-in**, a term originated by Netscape for application programs that can be activated within a Netscape Web **browser** window.

address

People use this word several ways. You can ask someone for the address of their **server**, or for their **home page** on the Web, or where to send **e-mail**. So an "address" can mean the

unique location of either (1) an Internet server, (2) a specific file (for example, a Web page), or (3) an e-mail user. It is also used to specify the location of data within computer **storage**.

1) An **Internet address** or IP address is a unique computer (**host**) location on the Internet (expressed either as a unique string of numbers or as its associated **domain name**).

Example of an IP address expressed in dot notation: 205.245.172.72

Example of the domain name version: `whatis.com`

For more information, see **IP address**.

2) A **file (or home page) address** is expressed as the defining directory path to the file on a particular server. (A Web page address is also called a Uniform Resource Locator, or **URL**.)

Example: `http://www.hitmill.com/computers/computerhx1.html`

3) An **e-mail address** is the location of an e-mail user (expressed by the user's e-mail name followed by an "at" sign followed by the user's server domain name.)

Example: `missmuffet@tuffet.org`

4) In a computer, a **storage address** is the beginning location of a sequence of data that is stored on some electronic storage medium.

Address Resolution Protocol

Address Resolution Protocol (ARP) is a **protocol** for mapping an Internet Protocol address (**IP address**) to a physical machine address that is recognized in the local network. For example, in IP Version 4, the most common level of IP in use today, an address is 32 bits long. In an **Ethernet** local area network, however, addresses for attached devices are 48 bits long. (The physical machine address is also known as a Media Access Control or **MAC address**.) A table, usually called the ARP cache, is used to maintain a correlation between each MAC address and its corresponding IP address. ARP provides the protocol rules for making this correlation and providing address conversion in both directions.

How ARP Works

When an incoming packet destined for a host machine on a particular local area network arrives at a **gateway**, the gateway asks the ARP program to find a physical host or MAC address that matches the IP address. The ARP program looks in the ARP cache and, if it finds the address, provides it so that the packet can be converted to the right packet length and format and sent to the machine. If no entry is found for the IP address, ARP broadcasts a request packet in a special format to all the machines on the LAN to see if one machine knows that it has that IP address associated with it. A machine that recognizes the IP address as its own returns a reply so indicating. ARP updates the ARP cache for future reference and then sends the packet to the MAC address that replied.

Since protocol details differ for each type of local area network, there are separate ARP Requests for Comments (RFC) for Ethernet, **ATM**, Fiber Distributed-Data Interface, HIPPI, and other protocols.

There is a Reverse ARP (**RARP**) for host machines that don't know their IP address. RARP enables them to request their IP address from the gateway's ARP cache.

address sign

See "at sign"

ad-hoc network

An ad-hoc (or "spontaneous") network is a **local area network** or other small network, especially one with **wireless** or temporary plug-in connections, in which some of the network devices are part of the network only for the duration of a communications session or, in the case of mobile or portable devices, while in some close proximity to the rest of the network. In Latin, *ad hoc* literally means "for this," further meaning "for this purpose only," and thus usually temporary. The term has been applied to future office or home networks in which new devices can be quickly added, using, for example, the proposed **Bluetooth** technology in which devices communicate with the computer and perhaps other devices using wireless transmission.

One vendor offers an ad-hoc network technology that allows people to come to a conference room and, using **infrared transmission** or radio frequency (**RF**) wireless signals, join their notebook computers with other conferees to a local network with shared data and printing resources. Each user has a unique network address that is immediately recognized as part of the network. The technology would also include remote users and hybrid wireless/wire connections.

Jini is an approach to instant recognition of new devices in a network that would seem to make it easier to have an ad-hoc network.

admittance

Admittance (symbolized Y) is an expression of the ease with which alternating current (**AC**) flows through a complex circuit or system. Admittance is a **vector** quantity comprised of two independent **scalar** phenomena: **conductance** and **susceptance**.

Conductance, denoted G , is a measure of the ease with which charge carriers can pass through a component or substance. The more easily the charge carriers move in response to a given applied electric potential, the higher the conductance, which is expressed in positive real-number **siemens**. Conductance is observed with AC and also with direct current (**DC**).

Susceptance, denoted B , is an expression of the readiness with which an electronic component, circuit, or system releases stored energy as the current and voltage fluctuate. Susceptance is expressed in **imaginary number** siemens. It is observed for AC, but not for DC. When AC passes through a component that contains susceptance, energy might be stored and released in the form of a magnetic field, in which case the susceptance is inductive (denoted $-jB_L$), or energy might be stored and released in the form of an electric field, in which case the susceptance is capacitive (denoted $+jB_C$).

Admittance is the vector sum of conductance and susceptance. Susceptance is conventionally multiplied by the positive square root of -1 , the unit imaginary number called symbolized by j , to express Y as a complex quantity $G - jB_L$ (when the net susceptance is inductive) or $G + jB_C$ (when the net susceptance is capacitive).

In parallel circuits, conductance and susceptance add together independently to yield the composite admittance. In series circuits, conductance and susceptance combine in a more complicated manner. In these situations, it is easier to convert conductance to resistance, susceptance to reactance, and then calculate the composite impedance.

Also see **conductance**, **reactance**, **resistance**, **impedance**, **ohm**, **siemens**, **henry**, and **farad**.

ADO

See “ActiveX Data Objects”

ADPCM

ADPCM (adaptive differential pulse-code modulation) is a technique for converting sound or **analog** information to **binary** information (a string of 0's and 1's) by taking frequent samples of the sound and expressing the value of the sampled sound modulation in binary terms. ADPCM is used to send sound on fiber-optic long-distance lines as well as to store sound along with text, images, and code on a CD-ROM.

ADSI

ADSI (Analog Display Services Interface) is the standard **protocol** for enabling alternate voice and data services, such as a visual display at the phone, over the **analog** telephone network. Developed by Bellcore in 1993, ADSI is now built into devices such as special telephones with small display screens, cable TV **set-top box**, personal digital assistants (PDAs), pagers, and personal computers with telephone applications.

A popular application enabled by ADSI is Call Waiting Deluxe, an application that displays the name and number of an incoming call while you are on the phone. If you have an ADSI screen phone, several options are displayed on your screen including switching to the new call, forwarding the

new call to your voice mail, putting the new caller on hold, playing a recorded message, or dropping the current call and switching to the new call.

Other ADSI applications include:

- Visual voice mail, the display of telephone voice mail menu options and a list of your voice mail messages
- Visual directory, a service that allows you to locate the telephone number of an individual or business and, possibly at extra charge, to download the address of that individual to your screen phone
- E-mail browsing, allowing you to send and receive e-mail messages via an ADSI-enabled device.
- Schedule-based services, faxing abilities, notification of incoming e-mail messages, home banking, ticket purchasing, and access to train and plane schedules

ADSL Terminal Unit—Remote

See “ATU-R”

ADSL

Also see **Fast Guide to DSL**.

ADSL (Asymmetric Digital Subscriber Line) is a technology for transmitting **digital** information at a high **bandwidth** on existing phone lines to homes and businesses. Unlike regular dialup phone service, ADSL provides continuously available, “always on” connection. ADSL is asymmetric in that it uses most of the channel to transmit downstream to the user and only a small part to receive information from the user. ADSL simultaneously accommodates **analog** (voice) information on the same line. ADSL is generally offered at downstream data rates from 512 **Kbps** to about 6 **Mbps**. A form of ADSL, known as Universal ADSL or **G.lite**, has been approved as a standard by the **ITU-TS**.

ADSL was specifically designed to exploit the one-way nature of most multimedia communication in which large amounts of information flow toward the user and only a small amount of interactive control information is returned. Several experiments with ADSL to real users began in 1996. In 1998, wide-scale installations began in several parts of the U.S. In 2000 and beyond, ADSL and other forms of DSL are expected to become generally available in urban areas. With ADSL (and other forms of DSL), telephone companies are competing with cable companies and their **cable modem** services.

ADSTAR Distributed Storage Management

ADSTAR Distributed Storage Management (ADSM) is a collective term for IBM's family of high-end software that helps a customer manage the storage devices (such as **mainframe** storage, PC disk drives, and Zip drives) that are scattered around the company.

ADSM helps medium and large companies automatically **back up** the business information in all of the storage devices throughout the enterprise. ADSM software works with a variety of database formats, including those made by IBM competitors.

The basic premise behind ADSM is to allow customers to view and manage storage as a single comprehensive endeavor. The idea is to let customers back up on an enterprise level, instead of having to save all the data residing in all the PCs, networks and other machines throughout a company at each individual location.

IBM is no longer actively selling ADSM software. Instead, IBM and its **Tivoli** subsidiary are selling Tivoli Storage Manager software as the ADSM successor.

Advanced Configuration and Power Interface

ACPI (Advanced Configuration and Power Interface) is an industry specification for the efficient handling of power consumption in desktop and mobile computers. ACPI specifies how a computer's **basic input/output system**, **operating system**, and **peripheral** devices communicate with each other about power usage.

With ACPI, the following capabilities are possible (assuming the operating system supports them):

- The user can specify at what time a device, such as a display monitor, is to turn off or on.
- The user of a notebook computer can specify a lower-level of power consumption when the battery starts running low so that essential applications can still be used while other, less important applications are allowed to become inactive.
- The operating system can lower the **clock speed** during times when applications don't require the full processor clock speed.
- The operating system can reduce motherboard and peripheral device power needs by not activating devices until they are needed.
- The computer can enter a *stand-by mode* when no one is using it, but with modem power left on to receive incoming faxes.
- Devices can be **plug and play**. As soon as plugged in, they can be controlled by ACPI.

ACPI must be supported by the computer **motherboard**, **basic input/output system** (BIOS), and the **operating system**. One of several *power schemes* can be chosen. Within a power scheme, the user can control the power to individual devices. In order for ACPI to work on your computer, your BIOS must include the ACPI software and the operating system must be ACPI-compatible. ACPI is designed to work with Windows 98 and with Windows 2000. If you have **Windows 98**, you'll find a description of ACPI in the help files. Click Start->Help->Index-> and type in: ACPI.

ACPI is in part a response to global concerns about energy conservation and environmental control. ACPI replaces Intel's SL technology and the more recent APM (Advanced Power Management) technology. Based on the collaborative effort of Intel, Toshiba, and Microsoft, ACPI moves away from power management that simply times out during inactivity to a more sophisticated demand-based power management. ACPI components collect information about power consumption from the computer and gives that information to the operating system. The operating system then distributes power to the different computer components on an as-needed basis. With ACPI, the computer can power itself down to a deep sleep state but still be capable of responding to an incoming phone call or a timed backup procedure. Another feature of ACPI is the "hibernation" mode. Before the computer goes into a deep sleep or hibernation, the contents of RAM are written to an image file and saved on the hard drive. When the computer is turned back on, the image file is reloaded, eliminating the need to reboot the system and open applications.

Advanced Encryption Standard

Also see **cryptography**.

The Advanced Encryption Standard (AES) is an **encryption algorithm** for securing sensitive but unclassified material by US Government agencies and, as a likely consequence, may eventually become the de facto encryption standard for commercial transactions in the private sector. (Encryption for the US military and other classified communications is handled by separate, secret algorithms.)

In January 1997, a process was initiated by the National Institute of Standards and Technology (NIST), a unit of the US Commerce Department, to find a more robust replacement for the Data Encryption Standard (DES) and to a lesser degree Triple DES. The specification called for a symmetric algorithm (same **key** for encryption and decryption) using block encryption (see **block cipher**) of 128 bits in size, supporting key sizes of 128, 192 and 256 bits, as a minimum. The algorithm was required to be royalty-free for use worldwide and offer security of a sufficient level to protect data for the next 20 to 30 years. It was to be easy to implement in hardware and software, as well as in restricted environments (for example, in a **smart card**) and offer good defenses against various attack techniques.

The entire selection process was fully open to public scrutiny and comment, it being decided that full visibility would ensure the best possible analysis of the designs. In 1998, the NIST selected 15 candidates for the AES, which were then subject to preliminary analysis by the world cryptographic community, including the National Security Agency. On the basis of this, in August 1999, NIST selected five algorithms for more extensive analysis. These were:

- MARS, submitted by a large team from IBM Research
- RC6, submitted by RSA Security
- Rijndael, submitted by two Belgian cryptographers, Joan Daemen and Vincent Rijmen
- Serpent, submitted by Ross Andersen, Eli Biham and Lars Knudsen
- Twofish, submitted by a large team of researchers including Counterpane's respected cryptographer, Bruce Schneier

Implementations of all of the above were tested extensively in **ANSI C** and **Java** languages for speed and reliability in such measures as encryption and decryption speeds, key and algorithm set-up time and resistance to various attacks, both in hardware- and software-centric systems. Once again, detailed analysis was provided by the global cryptographic community (including some teams trying to break their own submissions). The end result was that on October 2, 2000, NIST announced that Rijndael had been selected as the proposed candidate as the AES. After a 90 day period of public comment when the algorithm is presented as a Federal Information Processing Standard (**FIPS**), the Secretary of Commerce will approve it after final, detailed analysis. Final, official acceptance is expected some time in June 2001.

Advanced Function Printing

Advanced Function Printing (AFP) is an IBM architecture and family of associated printer software and hardware that provides document and information presentation control independent of specific applications and devices. Using AFP, users can control formatting, the form of paper output, whether a document is to be printed or viewed online, and manage document storage and access in a distributed network across multiple **operating system** platforms. AFP is primarily used in large **enterprises** with printer rooms and expensive high-speed printers. AFP applications allow users or print room operators to distributed print jobs among a group of printers and to designate backup printers when one fails. IBM considers AFP to be a "cornerstone" of **EDM** applications such as print-and-view, **archive** and retrieval, and Computer Output to Laser Disk (**COLD**).

AFP printer and software support is provided in all of IBM's major operating systems: **OS/390**, **virtual machine**, **VSE**, **OS/400**, **AIX**, and **OS/2**, as well as in **DOS** and **Windows**.

The AFP architecture is primarily designed to work with the Intelligent Printer Datastream (IPDS), but also can print using Hewlett-Packard's Printer Control Language (**PCL**) and the Page Printer Datastream (PPDS). Other supported data streams include **ASCII**, **Metafiles**, **Postscript**, **TeX**, and **Ditroff**.

An application program interface (**API**) is provided so that **COBOL** application programmers can use AFP functions without having to specify them using AFP **syntax** or semantics.

Advanced Intelligent Network

The Advanced Intelligent Network (AIN) is a telephone network architecture that separates service logic from switching equipment, allowing new services to be added without having to redesign switches to support new services. It encourages competition among service providers since it makes it easier for a provider to add services and it offers customers more service choices.

Developed by Bell Communications Research, AIN is recognized as an industry standard in North America. Its initial version, AIN Release 1, is considered a model toward which services will evolve. Meanwhile, evolutionary subsets of AIN Release 1 have been developed. These are shown in the (#ainrels) AIN Release Table below. Elsewhere, the International Telecommunications Union (see **ITU-TS**), endorsing the concepts of AIN, developed an equivalent version of AIN called Capability Set 1 (CS-1). It comes in evolutionary subsets called the Core INAP capabilities.

How It Works

Briefly, here's how AIN Release 1 works:

- A telephone caller dials a number that is received by a **switch** at the telephone company central office.
- The switch—known as the Service Switching Point (**SSP**)—forwards the call over a Signaling System 7 (**SS7**) network to a Service Control Point (**SCP**) where the service logic is located.
- The Service Control Point identifies the service requested from part of the number that was dialed and returns information about how to handle the call to the Service Switching Point. Examples of services that the SCP might provide include area number calling service, disaster recovery service, do not disturb service, and 5-digit extension dialing service.
- In some cases, the call can be handled more quickly by an Intelligent Peripheral (**IP**) that is attached to the Service Switching Point over a high-speed connection. For example, a customized voice announcement can be delivered in response to the dialed number or a voice call can be analyzed and recognized.

O

P

Q

R

S

T

U

V,W

X,Y,Z

- In addition, an “adjunct” facility can be added directly to the Service Switching Point for high-speed connection to additional, undefined services.

One of the services that AIN makes possible is Local Number Portability (**Local Number Portability**).

The AIN Release Table

AIN Release	Capabilities
Release 0	Trigger checkpoints at off-hook, digit collection and analysis, and routing points of call Code gapping to check for overload conditions at SCP 75 announcements at the switching system Based on ANSI TCAP issue 1
Release 0.1	Adds a formal call model that distinguishes the originating half of the call from the terminating half Additional triggers 254 announcements at the switching system Based on ANSI TCAP issue 2
Release 0.2	Adds Phase 2 Personal Communication Service (PCS) support Voice Activated Dialing (VAD) ISDN-based SSP-IP interface Busy and no-answer triggers Next events list processing at SCP Default routing
Release 1	A full set of capabilities

Advanced Mobile Phone Service

Advanced Mobile Phone Service (AMPS) is a standard system for **analog** signal **cellular telephone** service in the United States and is also used in other countries. It is based on the initial **electromagnetic radiation spectrum** allocation for cellular service by the Federal Communications Commission (FCC) in 1970. Introduced by AT&T in 1983, AMPS became and currently still is the most widely deployed cellular system in the United States.

AMPS allocates frequency ranges within the 800 and 900 megahertz (MHz) spectrum to cellular telephone. Each service provider can use half of the 824-849 MHz range for receiving signals from cellular phones and half the 869-894 MHz range for transmitting to cellular phones. The bands are divided into 30 kHz sub-bands, called *channels*. The receiving channels are called *reverse channels* and the sending channels are called *forward channels*. The division of the spectrum into sub-band channels is achieved by using frequency division multiple access (FDMA).

The signals received from a transmitter cover an area called a **cell**. As a user moves out of the cell's area into an adjacent cell, the user begins to pick up the new cell's signals without any noticeable transition. The signals in the adjacent cell are sent and received on different channels than the previous cell's signals so that the signals don't interfere with each other.

The analog service of AMPS has been updated with **digital** cellular service by adding to FDMA a further subdivision of each channel using time division multiple access (TDMA). This service is known as digital AMPS (**D-AMPS**). Although AMPS and D-AMPS originated for the North American cellular telephone market, they are now used worldwide with over 74 million subscribers, according to Ericsson, one of the major cellular phone manufacturers.

Advanced Peer-to-Peer Networking (APPN)

Advanced Peer-to-Peer Networking (APPN), part of IBM's Systems Network Architecture (SNA), is a group of protocols for setting up or configuring program-to-program communication within an IBM SNA network. Using APPN, a group of computers can be automatically configured by one of the computers acting as a network controller so that peer programs in various computers will be able to communicate with other using specified network routing.

APPN features include:

- Better **distributed** network control; because the organization is peer-to-peer rather than solely hierarchical, terminal failures can be isolated
- Dynamic peer-to-peer exchange of information about network **topology**, which enables easier connections, reconfigurations, and routing
- Dynamic definition of available network resources
- Automation of resource registration and directory lookup
- Flexibility, which allows APPN to be used in any type of network topology

How Dynamic Configuration Works

APPN works with Advanced Program-to-Program Communication (APPC) software that defines how programs will communicate with each other through two interfaces: one that responds to requests from **application** programs that want to communicate and one that exchanges information with communications hardware. When one program wants to communicate with another, it sends out a request (called an *allocate call*) that includes the destination's **logical unit** (LU) name—the APPC program on each computer that uniquely identifies it. APPC sets up a session between the originating and destination LUs.

APPN network **nodes** are differentiated as *low entry networking* (LEN) nodes, *end nodes* (ENs), and *network nodes* (NNs). When the network computers are powered on and

the software activated, links are established throughout the specified topology. The linked nodes exchange information automatically. If we consider a simplified APPN network, with one end node connected to a network node, the following would describe the sequence of events:

- Each node indicates APPN capability and defines its node type.
- The network node asks the end node if it requires a network node server, which handles requests for LU locations.
- If it responds that it does, the two nodes establish APPC sessions to exchange program-to-program information.
- The end node registers any other LUs defined at its node by sending the networked node formatted information gathered from the APPC session.
- After this sequence is completed, the network node knows the location of the EN and what LUs are located there. This information, multiplied across the network, enables LU location and routing.

Advanced Program-to-Program Communication

See “APPC”

Advanced Television

See “ATV”

Advanced Television Enhancement Forum

The Advanced Television Enhancement Forum (ATVEF) is an alliance of leaders in the broadcast and cable industry, the consumer electronics industry, and the computer industry that developed the ATVEF enhanced content specification. The ATVEF specification delivers Web content to television viewers using current Internet technologies over both **analog** and digital television (DTV) systems. ATVEF uses existing terrestrial, cable, satellite, and Internet networks to deliver Web content. ATVEF content is broadcast over one-way or two-way television systems. Supported files include Hypertext Markup Language (HTML), Virtual Reality Modeling Language (VRML), Java, and private data files. Consumers can receive Web content using a personal computer, cable or satellite **set-top box**, or **WebTV** device.

The ATVEF specification consists of three parts: the announcement, trigger, and content:

- The announcement notifies the television viewer of any current Web content available and expires after a set time period. The announcement also includes information that helps the set-top box to decide whether to accept the Web content or to determine whether the Web content is designed to automatically begin without authorization.

- The trigger contains the URL that points to the Web content.
- The content delivered is a collection of Web pages that is displayed along with the television program. It can include text, pictures, and audio files. If the television system is a two-way system, the viewer can browse Web pages and even purchase advertised items using his television.

The ATVEF specification also defines a degree of forward error correction. The data to be transmitted is processed through an **algorithm** that adds extra bits for error correction. If the Web content is damaged during transmission, the extra bits are used to correct the damage. It also allows the data to be reconstructed if received out of order. The forward error correction defined by the ATVEF specification also allows a viewer to receive Web content even if the viewer has tuned into the middle of a broadcast.

Advanced Television Systems Committee

The Advanced Television Systems Committee (ATSC) is a standards organization that was created in 1982 as part of the Advanced Television Committee (ATV) to promote the establishment of technical standards for all aspects of advanced television systems. Based in Washington, D.C., ATSC has grown from 25 original organizational members to an international membership of over 200, including broadcasters, motion picture companies, telecommunications carriers, cable TV programmers, consumer electronics manufacturers, and computer hardware and software companies.

The ATSC developed standards for digital television (DTV) that specify technologies for the transport, format, compression, and transmission of DTV in the U.S. ATSC DTV Standards developed, or in development currently, include digital high definition television (term>>HDTV), standard definition television (SDTV), datacasting (the transmission of separate information streams that might allow, for example, someone watching a baseball game to choose a different camera angle, or someone watching a cooking show to view and download particular recipes), multichannel surround-sound audio, **conditional access** (methods, such as encryption or electronic locking systems, used to restrict service access to authorized users), and interactive services. For SDTV and HDTV, ATSC chose **MPEG-2** for video and **Dolby Digital** for audio.

ATSC standards are expected to revolutionize the television industry as defined by the National Television Standards Committee (NTSC) standards set in 1953. ATSC standards for DTV are being adopted internationally.

AES/EBU

AES/EBU (Audio Engineering Society/European Broadcasting Union) is the name of a **digital audio** transfer standard. The AES and EBU developed the specifications for the standard.

The AES/EBU digital interface is usually implemented using 3-pin XLR connectors, the same type connector used in a professional microphone. One cable carries both left- and right-channel audio data to the receiving device. AES/EBU is an alternative to the S/PDIF standard.

AF

See also **RF** (radio frequency).

AF (audio frequency) (also abbreviated af or a.f.) refers to alternating current (**AC**) having a frequency such that, if applied to a transducer such as a loudspeaker or headset, it will produce acoustic waves within the range of human hearing. The AF range is generally considered to be from 20 Hz to 20,000 Hz.

All telephone circuits operate with AF signals in a restricted range of approximately 200 Hz to 3000 Hz. A telephone-line **modem** is an AF device that converts binary **digital** data into **analog** signals that can be transmitted over the telephone circuit, and also converts incoming AF signals into binary digital data.

AFC

AFM

See "atomic force microscope"

AFS

See "Andrew file system"

agent

On the Internet, an agent (also called an **intelligent agent**) is a program that gathers information or performs some other service without your immediate presence and on some regular schedule. Typically, an agent program, using parameters you have provided, searches all or some part of the Internet, gathers information you're interested in, and presents it to you on a daily or other periodic basis.

An example of an agent is Infogate, which alerts you about news on specified topics of interest. A number of similar agents compare shopping prices and bring the news back to the user. Other types of agents include specific site watchers that tell you when the site has been updated or look for other events and analyst agents that not only gather but organize and interpret information for you.

An agent is sometimes called a **bot** (short for robot). The practice or technology of having information brought to you by an agent is sometimes referred to as **push** technology.

aggregate

In general, to aggregate (verb, from Latin *aggregare* meaning to add to) is to collect things together. An aggregate (adjective) thing is a collection of other things. An aggregation is a collection.

In information technology, individual items of data are sometimes aggregated into a database. Unlike **marshalling**, aggregation doesn't require giving one thing precedence over another thing.

aggregator

Like its synonym **concentrator**, an aggregator is any **device** that serves multiple other devices or users either with its own capabilities or by forwarding transmissions in a more concentrated and economical way. A remote access **hub** is sometimes referred to as an aggregator. A typical aggregator or remote access hub is a device that handles incoming dial-up calls for an Internet (or other network) **POP** and performs other services. An aggregator may be able to handle up to 100 dial-up modem calls, support a certain number of **Integrated Services Digital Network** connections, and support **leased line** and **frame relay** traffic while also functioning as a **router**.

aglet

1) In computer technology, an aglet (or "agile applet") is a small application program or **applet** with the capability to serve as a mobile **agent** of services in a computer network. An aglet has these characteristics:

- **Object-passing capability.** It is a complete program **object** with its own methods, data states, and travel itinerary that can send other aglets or pass itself along in a network as an entity.
- **Autonomous.** An aglet has the ability to decide on its own what actions to take and where and when to go elsewhere.
- **Interaction with other program objects.** It can interact locally with other aglets or stationary objects. When necessary, it can dispatch itself or other aglets to remote locations to interact with other objects there.
- **Disconnected operation.** If a computer is currently disconnected from the network, the aglet can schedule itself to move when the computer is reconnected.
- **Parallel execution.** Multiple aglets can be dispatched to run concurrently in different computers.

An aglet is a **class** or template in the **Java object-oriented programming** language and the mobile agent instances of its use are also called aglets.

Relatively simple examples of aglets are applications in which one aglet can dispatch another to a remote computer to display a note or to search for information and send it back or to notify a user on another computer that a page had changed. Much more complicated applications are envisioned (or are waiting to be envisioned).

The term apparently originated at IBM's research laboratory in Japan. IBM offers a free Aglets Workbench, which is a visual programming environment for creating aglets. IBM has also created an application program interface, the Agent Transfer Protocol (ATP), for transferring agents between networked computers. Both the Agent Transfer Protocol and the Workbench framework protocol have been offered to the Object Management Group (OMG), an industry standards body, as a proposal for a standard Mobile Agent Facility. IBM is offering the Workbench free to developers.

2) An aglet is also the small plastic or fiber tube that binds the end of a shoelace (or similar cord) to prevent fraying and to allow the lace to be passed through an eyelet or other opening.

AGP

See "Accelerated Graphics Port"

Ah

See "ampere hour"

AHA

See "Accelerated Hub Architecture"

AI

AI (pronounced AYE-EYE) or artificial intelligence is the simulation of human intelligence processes by machines, especially computer systems. These processes include learning (the acquisition of information and rules for using the information), reasoning (using the rules to reach approximate or definite conclusions), and self-correction. Particular applications of AI include expert systems, **speech recognition**, and **machine vision**.

AIBO

AIBO (pronounced eye-bow) is an entertainment **robot** designed by Sony. AIBO means "companion" in Japanese. It is also an abbreviation for "artificial intelligence bot" ("**bot**" is short for "robot") in English. Sony created AIBO to be a robotic pet and promotes AIBO as having the capability to interact with its human owner in many of the same ways a living pet would—without the high maintenance.

Sony classifies AIBO as an **autonomous robot**, meaning that it has the ability to learn, mature, and act on its own in response to external stimuli. AIBO has a brain (**CPU**), the ability to move (20 points of articulation), and sensory

organs (sensors). AIBO's developmental stages are controlled by a "memory stick" application software. Human interaction with AIBO determines its ability to express its needs and emotions, as well as its ability to learn and mature. AIBO is capable of expressing happiness, sadness, anger, surprise, fear and dislike. Just like a pet that's alive, the more interaction AIBO has with humans, the faster it learns.

AIBO's head has a touch sensor for non-verbal communication, stereo microphones for hearing, a color video camera for vision, and a distance detector to allow AIBO to avoid obstacles. AIBO has **voice recognition** components that allow AIBO to be programmed to recognize its own name and understand over 50 verbal commands (depending on where AIBO is in its growth cycle). At present, AIBO is bi-lingual and understands Japanese and English; Sony plans to add German and French to increase the robot's worldwide appeal. AIBO is able to communicate with humans by emitting musical tones and changing the color and shape of its eyes. AIBO can be "taught" to play games, but unlike a game, AIBO cannot be reset.

AIBO uses Sony's OPEN-R platform to operate. OPEN-R is modular, so the robot's hardware and software components can be easily changed. Sony plans to initiate a licensing program that will allow developers to use OPEN-R technology to create new applications for AIBO. They hope that opening up development will encourage the public's acceptance of personal robots and help create a broad base of consumers interested in purchasing entertainment or household-helper robots. SONY has released two models of AIBO. The first version of AIBO resembled a dog. The second version of AIBO is said to be modeled after a lion cub. The basic AIBO model sells in the United States for \$1,500. The deluxe version, which comes with a charging station, carrying bag, extra battery and additional software package sells for \$2,800.

AIFF

AIFF (Audio Interchange File Format) is one of the two most-used **audio file** formats used in the Apple **Macintosh operating system**. The other is Sound Designer II (SDII). Most CD writers can accept AIFF or SDII files interchangeably when writing a Red Book audio CD. AIFF is sometimes referred to as "Apple Interchange File Format."

The extension for this file type is ".aif" when it is used on a PC. On a Mac, the file extension is not needed. A Mac file uses a Type and Creator resource to identify itself to the operating system and the applications that can open it.

An AIFF file contains the raw audio data, channel information (monophonic or stereophonic), bit depth, **sample rate**, and application-specific data areas. The application-specific data areas let different applications add information to the file header that remains there even if the file is opened and processed by another application. For

air interface

In **cellular telephone** communications, the air interface is the radio-frequency portion of the circuit between the cellular phone set or wireless modem (usually portable or mobile) and the active base station. As a subscriber moves from one cell to another in the system, the active base station changes periodically. Each changeover is known as a **handoff**.

A cellular connection is only as good as its weakest link, which is almost always the air interface. Radio-frequency (**RF**) circuits are subject to many variables that affect signal quality. Factors that can cause problems include:

- Use of the handheld phone set or portable wireless modem inside buildings, cars, buses, trucks, or trains
- Proximity to human-made, steel-frame obstructions, especially large buildings and freeway overpasses
- Abundance of utility wires that can reflect radio signals and/or generate noise that interferes with reception
- Irregular terrain, particularly canyons and ravines
- Inadequate transmitter power in phone set or wireless modem
- Poorly designed antenna in phone set or wireless modem

In addition to these variables, some cellular networks have inadequate coverage in certain geographic areas. Usually this is because there are not enough base stations to ensure continuous communications for subscribers using portable (handheld) phone sets. As a network evolves, more base stations may be installed in a given region, and in that case, this problem will diminish with time. Conversion of a network from analog to digital can result in dramatic improvement.

AIX

AIX is an **open** operating system from IBM that is based on a version of **UNIX**. AIX/ESA was designed for IBM's System/390 or large server hardware platform. AIX/6000 is an operating system that runs on IBM's workstation platform, the RISC System/6000.

algebraic number

An algebraic number is any **real number** that is a solution of some single-variable **polynomial** equation whose **coefficients** are all **integers**. While this is an abstract notion, theoretical mathematics has potentially far-reaching applications in communications and computer science, especially in data **encryption** and security.

The general form of a single-variable polynomial equation is:

$$a_0 + a_1x + a_2x^2 + a_3x^3 + \dots + a_nx^n = 0$$

where $a_0, a_1, a_2, \dots, a_n$ are the coefficients, and x is the unknown for which the equation is to be solved. A number x is algebraic if and only if there exists some equation of the above form such that $a_0, a_1, a_2, \dots, a_n$ are all integers.

All **rational numbers** are algebraic. Examples include 25, $\frac{7}{9}$, and -0.245245245. Some **irrational numbers** are also algebraic. Examples are $2^{1/2}$ (the square root of 2) and $3^{1/3}$ (the cube root of 3). There are irrational numbers x for which no single-variable, integer-coefficient polynomial equation exists with x as a solution. Examples are **π** (the ratio of a circle's circumference to its diameter in a plane) and e (the natural **logarithm** base). Numbers of this type are known as **transcendental numbers**.

algorithm

The term algorithm (pronounced AL-go-rith-um) is a procedure or formula for solving a problem. The word derives from the name of the mathematician, Mohammed ibn-Musa Al-Khowarizmi, who was part of the royal court in Baghdad and who lived from about 780 to 850. Al-Khowarizmi's work is the likely source for the word *algebra* as well.

A computer **program** can be viewed as an elaborate algorithm. In mathematics and computer science, an algorithm usually means a small procedure that solves a recurrent problem.

alias

In general, as a noun, an alias (pronounced AY-lee-uhs) is an alternate name for someone or something. In literature, a "pen name" is an alias for the author's real name. The noun is derived from the Latin adverb *alias*, meaning "otherwise" and by extension "otherwise known as" and the latter meaning is still used in English, as in: Clark Kent, alias Superman. In information technology, the noun has at least two different usages.

1) In some computer **operating systems** and programming languages, an alias is an alternative and usually easier-to-understand or more significant name for a defined data object. The data object can be defined once and later a programmer can define one or more equivalent aliases that will also refer to the data object. In some languages, this is known as an "equate" instruction.

2) In **Macintosh** operating systems, an alias is a **desktop icon** for a particular program or data object.

aliasing

In sound and image generation, aliasing is the generation of a false (alias) frequency along with the correct one when doing frequency sampling. For images, this produces a jagged edge, or stair-step effect. For sound, it produces a buzz.

See **antialiasing**.

Aloha

Aloha, also called the *Aloha method*, refers to a simple communications scheme in which each source (transmitter) in a network sends data whenever there is a **frame** to send. If the frame successfully reaches the destination (receiver), the next frame is sent. If the frame fails to be received at the destination, it is sent again. This protocol was originally developed at the University of Hawaii for use with **satellite** communication systems in the Pacific.

In a **wireless** broadcast system or a half-duplex two-way link, Aloha works perfectly. But as networks become more complex, for example in an **Ethernet** system involving multiple sources and destinations that share a common data path, trouble occurs because data frames collide (conflict). The heavier the communications volume, the worse the collision problems become. The result is degradation of system efficiency, because when two frames collide, the data contained in both frames is lost.

To minimize the number of collisions, thereby optimizing network efficiency and increasing the number of subscribers that can use a given network, a scheme called *slotted Aloha* was developed. This system employs signals called beacons that are sent at precise intervals and tell each source when the channel is clear to send a frame. Further improvement can be realized by a more sophisticated protocol called Carrier Sense Multiple Access with Collision Detection (**CSMA/CD**).

Alpha

Alpha is both a **microprocessor** and the name of a computer system from the Digital Equipment Corporation (DEC), which is now part of Compaq. The Alpha processor uses a newer and more advanced architecture than DEC's flagship computer line, the **VAX**. The Alpha is based on **reduced instruction set computer** (reduced instruction set computing) architecture and handles 64 bits at a time. DEC has added its own refinements to the RISC architecture to further increase performance.

The latest models of DEC's Alpha computer systems are offered with either DEC's **UNIX** operating system or with **Windows NT**. (DECUS states that DEC's **OpenVMS** also runs on Alpha computers.) DEC offers its AlphaServer

together with a packaged solution with Digital's **AltaVista** search engine for indexing and searching data within an enterprise's **intranet**. Its AlphaStation line offers personal workstations in the \$4-8,000 range.

alt.

See "alternate newsgroup"

AltaVista

AltaVista is a popular **search engine** on the Web. In addition to full-text searches, AltaVista can also search graphic images and tell you who is linked to your own Web pages. AltaVista's search robot, known as **Scooter**, can look at and collect data from three million Web pages per day. Its indexer, **Ni2**, indexes one gigabyte of data per hour.

alternate newsgroup

"alt." is the prefix for any of the hundreds of "alternate" user-originated **newsgroups** that are part of **Usenet**. Like other newsgroups, each "alt." newsgroup is arranged in a hierarchy of topical discussion boards that you may read or post to. "alt" is one of many major newsgroups; others include: news, rec (recreation), comp (computers), and soc (social). The "alt" newsgroups are known (and used most frequently) for their alt.sex and related categories, but are also known for including a wide and inventive range of discussion topics.

The easiest way to get access to newsgroups is through the Google Web site.

alternating current

Also see **current**, **voltage**, and **direct current**.

In electricity, alternating current (AC) occurs when charge carriers in a conductor or **semiconductor** periodically reverse their direction of movement. Household utility current in most countries is AC with a **frequency** of 60 **hertz** (60 complete cycles per second), although in some countries it is 50 Hz. The radio-frequency (**RF**) current in antennas and transmission lines is another example of AC.

An AC **waveform** can be sinusoidal, square, or sawtooth-shaped. Some AC waveforms are irregular or complicated. An example of sine-wave AC is common household utility current (in the ideal case). Square or sawtooth waves are produced by certain types of electronic oscillators, and by a low-end uninterruptible power supply (**UPS**) when it is operating from its battery. Irregular AC waves are produced by audio amplifiers that deal with analog voice signals and/or music.

The **voltage** of an AC power source can be easily changed by means of a power transformer. This allows the voltage to be stepped up (increased) for transmission and distribution.

V,W

X,Y,Z

High-voltage transmission is more efficient than low-voltage transmission over long distances, because the loss caused by conductor **resistance** decreases as the voltage increases.

The voltage of an AC power source changes from instant to instant in time. The *effective voltage* of an AC utility power source is usually considered to be the DC voltage that would produce the same power dissipation as heat assuming a pure resistance. The effective voltage for a sine wave is not the same as the *peak voltage*. To obtain effective voltage from peak voltage, multiply by 0.707. To obtain peak voltage from effective voltage, multiply by 1.414. For example, if an AC power source has an effective voltage of 117 V, typical of a household in the United States, the peak voltage is 165 V.

AM

See "amplitude modulation"

amateur radio

Amateur radio, also known as ham radio, is a hobby enjoyed by several hundred thousand people in the United States and by over a million people worldwide. Amateur radio operators call themselves "radio hams" or simply "hams."

To become a radio ham, you must pass an examination. Wireless amateur communication is done on numerous bands (relatively narrow frequency segments) extending from 1.8 MHz (a **wavelength** of about 160 meters) upwards through several hundred gigahertz (wavelengths in the millimeter range). There are several license classes. The more privileges a class of license conveys, the more difficult is the examination that one must pass to obtain it.

Amateur radio operation is fun, and that is one of the main reasons hams do it. But ham radio can provide communication during states of emergency. Ham radio works when all other services fail. After Hurricane Andrew struck South Florida in 1992, the utility grid was destroyed over hundreds of square miles. All cellular towers and antennas were blown down. Only amateur radio, the Citizens Radio Service ("Citizens Band"), and a few isolated pay phones with underground lines provided communication between the outside world and the public in the affected area.

Amateur radio operators are known as technical innovators, and have been responsible for important discoveries. For example, in the early part of the 20th century, government officials believed that all the frequencies having wavelengths shorter than 200 meters (1.5 MHz) were useless for radio communications, so they restricted radio amateurs to these frequencies. It was not long before ham radio operators discovered the truth, and were communicating on a worldwide scale using low-power transmitters. Thus the shortwave radio era began.

Amaya

Amaya is the Web **browser** that was developed by members of the World Wide Web Consortium (**W3C**) as a practical tool as well as a testing ground for W3C ideas. Amaya includes an **HTML** editor as well as a viewer and can be downloaded freely from the W3C Web site for use in either Linux or Windows 95/NT/2000 **operating system**. Amaya is distributed as **open source software**, meaning that software developers are free to add to or modify its code and extend its capabilities.

According to Web inventor and W3C Director Tim Berners-Lee, Amaya was developed because at the time no commercially available browser included editing capabilities. The idea was to develop the browser as a way to see why such capabilities hadn't been provided and perhaps help solve any problems that were in the way. Amaya also offers a testing platform for other W3C developments such as MathML, a user interface for creating complex mathematical expressions. Berners-Lee and staff members use Amaya as their primary browser.

Here are some interesting features of Amaya:

- A what-you-see-is-what-you-get (**WYSIWYG**) authoring interface similar to that of commercial products such as Microsoft's FrontPage and the ability to upload the pages to a server
- Support for the latest level of HTML, **XHTML**
- The ability to work on either the coded HTML view or the WYSIWYG source view of the page
- Special support for people with disabilities
- Assurance that the Web page you create will be properly constructed so that other tools will know what to expect when they work with your page
- Assistance in creating and viewing hypertext links
- The ability to display images in the **Portable Network Graphics** format, a more capable graphic format than the **Graphics Interchange Format** format that is also free from licensing requirements
- The ability to print the table of contents or the table of links in a document
- An application program interface (**API**) in **C** for adding new functions or modifying existing ones. Amaya is also used within the W3C to experiment with the **Java** API used in the Document Object Model (**DOM**)

Amaya is the **client** counterpart to the W3C's experimental Web **server**, *Jigsaw* (but you don't need Jigsaw to use Amaya).

AMD

AMD is the second largest maker of personal computer **microprocessors** after Intel. They also make **flash memory**, integrated circuits for networking devices, and program-

mable logic devices. AMD reports that it has sold over 100 million x86 (Windows-compatible) microprocessors. Its **Athlon** (formerly called the “K7”) microprocessor, delivered in mid-1999, was the first to support a 200 **MHz bus**. In March 2000, AMD announced the first 1 **gigahertz** PC microprocessor in a new version of the Athlon.

Founded in 1969, AMD along with **Cyrix** has often offered computer manufacturers a lower-cost alternative to the microprocessors from Intel. AMD develops and manufactures its processors and other products in facilities in Sunnyvale, California, and Austin, Texas. A new fabrication facility was opened in Dresden, Germany, in 1999.

The lower cost of AMD’s microprocessors was a contributor to lower PC prices in the 1998-2000 period. Reviewers generally rated the K6 and Athlon equivalent to or slightly better than comparable Pentium microprocessors from Intel. In addition to “the first mainstream 200 MHz system bus,” Athlon includes a superscalar **pipelining floating point unit**, and a programmable **L1 and L2**. The Athlon uses AMD’s aluminum 0.18 **micron** technology.

Amdahl’s law

In computer programming, Amdahl’s law is that, in a program with **parallel processing**, a relatively few **instructions** that have to be performed in sequence will have a limiting factor on program speedup such that adding more **processors** may not make the program run faster. This is generally an argument against parallel processing for certain applications and, in general, against overstated claims for parallel computing. Others argue that the kinds of applications for which parallel processing is best suited tend to be larger problems in which scaling up the number of processors does indeed bring a corresponding improvement in throughput and performance.

AMD-K6

See “K6”

American National Standards Institute

See “ANSI”

American Registry of Internet Numbers

The American Registry of Internet Numbers (ARIN) is the organization in the U.S. that manages **IP address** numbers for the U.S. and assigned territories. Because Internet addresses must be unique and because address space on the Internet is limited, there is a need for some organization to control and allocate address number blocks. IP number management was formerly a responsibility of the Internet Assigned Numbers Authority (IANA), which contracted with Network Solutions Inc. for the actual services. In December 1997, IANA turned this responsibility over to

ARIN, which, along with Reseaux IP Europeens (RIPE) and Asia Pacific Network Information Center (APNIC), now manages the world’s Internet address assignment and allocation. **Domain name** management is still the separate responsibility of Network Solutions and a number of other registrars accredited by the Internet Corporation for Assigned Names and Numbers (ICANN).

For Internet Protocol Version 6 (**IPv6**), which extends the length of an Internet address from 32 bits to 128 bits, ARIN will have many more addresses to manage and allocate.

American Wire Gauge

American Wire Gauge (AWG) is a U.S. standard set of non-ferrous wire conductor sizes. The “gauge” means the diameter. Non-ferrous includes copper and also aluminum and other materials, but is most frequently applied to copper household electrical wiring and telephone wiring. Typical household wiring is AWG number 12 or 14. Telephone wire is usually 22, 24, or 26. The higher the gauge number, the smaller the diameter and the thinner the wire. Since thicker wire carries more current because it has less electrical resistance over a given length, thicker wire is better for longer distances. For this reason, where extended distance is critical, a company installing a network might prefer telephone wire with the lower-gauge, thicker wire of AWG 24 to AWG 26.

AWG is sometimes known as Brown and Sharpe (B&S) Wire Gauge.

Amiga

Amiga is a personal computer designed especially for high-resolution, fast response graphics and multimedia applications. Its **microprocessor** is based on Motorola’s 680x0 line of processors. It was one of the first computers to offer **true color**. It comes with its own **operating system**, AmigaOS. Since its first appearance from Commodore Business Machines in 1985, Amiga has become a synonym for fast, high-resolution graphics and best known for its quickly responsive user interface and suitability for playing action games. AmigaOS handles 32-bit instructions and uses **preemptive multitasking**. Its design favors user input to the extent that it is sometimes described as a realtime operating system (RTOS).

Since Amiga was designed as a special-purpose system, AmigaOS, which is written in **C** and **assembler** language, is especially compact. All versions of the operating system will run on 512 **kilobytes** of **RAM**. All versions of the Amiga can run at 50 **MHz** or faster, using an accelerator card. A G4 processor can be used through adding an accelerator card. The Amiga supports **plug and play** and can be adapted with software to emulate Windows and Mac OS.

The Amiga has the ability to become a video monitor by locking into a video signal from an external source such as a video camera. As a result, Amigas are used by television stations and sports arenas to display video clips on large screens.

Amiga is working on a "Next Generation" system that will use **Linux** as its basic core. (Earlier plans favored another operating system, QNX.)

amp hour

See "ampere hour"

ampere

An ampere is a unit of measure of the rate of **electron** flow or **current** in an electrical conductor. One ampere of current represents one coulomb of electrical charge (6.24×10^{18} charge carriers) moving past a specific point in one second. Physicists consider current to flow from relatively positive points to relatively negative points; this is called conventional current or Franklin current.

The ampere is named after Andre Marie Ampere, French physicist (1775-1836).

ampere hour

An ampere hour (abbreviated Ah, or sometimes amp hour) is the amount of energy charge in a **battery** that will allow one **ampere** of **current** to flow for one hour.

A milliampere hour (mAh) is 1,000th of an Ah, and is commonly used as a measure of charge in portable computer batteries. The mAh provides an indication of how long the PC will operate on its battery without having to recharge it.

ampere per meter

The **ampere per meter** (symbolized A/m) is the International Unit of **magnetic field** strength. It is derived from basic standard units, but is expressed directly in base units and cannot be further reduced.

Consider the interior of a long, cylindrical coil with a single winding and an air core. Suppose that the linear **current** density in this coil is 1 ampere per meter of displacement as measured along the coil axis. (This expression differs from current density per unit area, which is expressed in **amperes per meter squared**.) Then the magnetic field strength in the interior of the coil is defined as 1 A/m.

For a given coil, the magnetic field strength is directly proportional to the linear current density. Thus, if the linear current density doubles, so does the magnetic field strength; if the linear current density becomes $1/10$ as great, the magnetic field strength also diminishes by a factor of 10.

Sometimes, magnetic field strength is expressed in units called oersteds (symbolized Oe). The oersted is a larger unit than the ampere per meter. Approximate conversions are:

$$1 \text{ Oe} = 79.578 \text{ A/m}$$

$$1 \text{ A/m} = 0.012566 \text{ Oe}$$

Also see **ampere**, **current**, **magnetic field**, **meter**, and International System of Units (SI).

ampere per meter squared

The ampere per meter squared, symbolized A/m^2 , is the International Unit of electric **current density**. A current density of 1 A/m^2 represents one **ampere** of electric **current** flowing through a material with a cross-sectional area of one square meter.

The ampere per meter squared is a small unit of current density. Suppose a wire has a cross-sectional area of one millimeter squared (1 mm^2). This is 0.000001 meter squared (10^{-6} m^2). If the current density in this wire is 1 A/m^2 , then the wire carries 10^{-6} A , or one microampere ($1 \mu\text{A}$), a tiny current. Suppose this same wire carries a current of one ampere (1 A), which is an entirely plausible scenario. Then the current density in the wire is 1,000,000 amperes per meter squared (10^6 A/m^2).

Sometimes, larger units of current density are specified. For example, one ampere per millimeter squared (A/mm^2) represents a current of 1 A flowing through a conductor with a cross-sectional area of 1 mm. This unit is equal to 1,000,000 (10^6) A/m^2 . One milliampere per millimeter squared (mA/mm^2) represents a current of 1 mA flowing through a conductor with a cross-sectional area of 1 mm. This unit is equal to 1,000 (10^3) A/m^2 .

Determination of current density is straightforward in direct-current (**DC**) and low-frequency alternating-current (**AC**) circuits, because the current is distributed uniformly throughout the cross section of a solid conductor. But at radio frequencies (**RF**), more current flows near the outer surface of a solid conductor than near its center. This is known as **skin effect**, and it dramatically reduces the conductivity of wires in RF applications as compared with DC and low-frequency AC circuits. At RF, current density is sometimes near zero near the center of a solid conductor,

and quite high near the outer periphery. The average current density can nevertheless be calculated according to the following formula:

$$D = I/X$$

where D is the current density in amperes per meter squared, I is the current in amperes, and X is the cross-sectional area of the conductor in meters squared.

Also see **ampere**, **meter squared**, **skin effect**, and International System of Units (SI).

amplification factor

The amplification factor, also called *gain*, is the extent to which an **analog amplifier** boosts the strength of a **signal**. Amplification factors are usually expressed in terms of **power**.

The **decibel** (dB), a **logarithmic** unit, is the most common way of quantifying the gain of an amplifier. For power, doubling the signal strength (an output-to-input power ratio of 2:1) translates into a gain of 3 dB; a tenfold increase in power (output-to-input ratio of 10:1) equals a gain of 10 dB; a hundredfold increase in power (output-to-input ratio of 100:1) represents 20 dB gain. If the output power is less than the input power, the amplification factor in decibels is negative. If the output-to-input signal power ratio is 1:1, then the amplification factor is 0 dB.

Power amplifiers typically have gain figures from a few decibels up to about 20 dB. Sensitive amplifiers used in **wireless** communications equipment can show gain of up to about 30 dB. If higher gain is needed, amplifiers can be cascaded, that is, hooked up one after another. But there is a limit to the amplification that can be attained this way. When amplifiers are cascaded, the later circuits receive noise at their inputs along with the signals. This noise can cause distortion. Also, if the amplification factor is too high, the slightest feedback can trigger oscillation, rendering an amplifier system inoperative.

amplifier

An amplifier is an electronic device that increases the **voltage**, **current**, or **power** of a **signal**. Amplifiers are used in **wireless** communications and broadcasting, and in **audio** equipment of all kinds. They can be categorized as either *weak-signal amplifiers* or *power amplifiers*.

Weak-signal amplifiers are used primarily in wireless receivers. They are also employed in acoustic pickups, audio tape players, and compact disc players. A weak-signal amplifier is designed to deal with exceedingly small input signals, in some cases measuring only a few nanovolts (units of 10^{-9} volt). Such amplifiers must generate minimal internal noise while increasing the signal voltage by a large factor. The most effective device for this application is the **field-effect transistor**. The specification that denotes the effectiveness of a weak-signal amplifier is *sensitivity*, defined

as the number of microvolts (units of 10^{-6} volt) of signal input that produce a certain ratio of signal output to noise output (usually 10 to 1).

Power amplifiers are used in wireless transmitters, broadcast transmitters, and hi-fi audio equipment. The most frequently-used device for power amplification is the **bipolar transistor**. However, vacuum tubes, once considered obsolete, are becoming increasingly popular, especially among musicians. Many professional musicians believe that the **vacuum tube** (known as a “valve” in England) provides superior fidelity.

Two important considerations in power amplification are *power output* and *efficiency*. Power output is measured in watts or kilowatts. Efficiency is the ratio of signal power output to total power input (wattage demanded of the power supply or battery). This value is always less than 1. It is typically expressed as a percentage. In audio applications, power amplifiers are 30 to 50 percent efficient. In wireless communications and broadcasting transmitters, efficiency ranges from about 50 to 70 percent. In hi-fi audio power amplifiers, *distortion* is also an important factor. This is a measure of the extent to which the output waveform is a faithful replication of the input **waveform**. The lower the distortion, in general, the better the fidelity of the output sound.

amplitude modulation

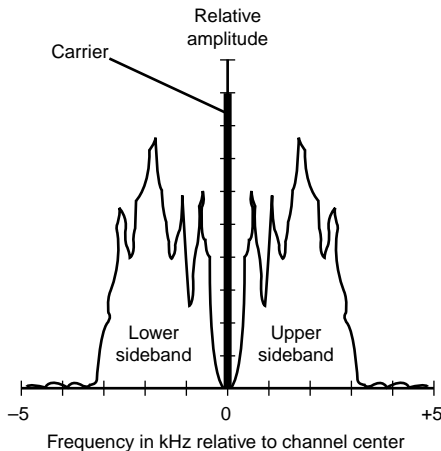

Also see **modulation**.

Amplitude modulation (AM) is a method of impressing data onto an alternating-current (AC) **carrier waveform**. The highest **frequency** of the modulating data is normally less than 10 percent of the carrier frequency. The instantaneous amplitude (overall signal power) varies depending on the instantaneous amplitude of the modulating data.

In AM, the carrier itself does not fluctuate in amplitude. Instead, the modulating data appears in the form of signal components at frequencies slightly higher and lower than that of the carrier. These components are called *sidebands*. The lower **sideband** (LSB) appears at frequencies below the carrier frequency; the upper sideband (USB) appears at frequencies above the carrier frequency. The LSB and USB are essentially “mirror images” of each other in a graph of signal amplitude versus frequency, as shown in the illustration. The sideband power accounts for the variations in the overall amplitude of the signal.

When a carrier is amplitude-modulated with a pure sine wave, up to $1/3$ (33 percent) of the overall signal power is contained in the sidebands. The other $2/3$ of the signal power is contained in the carrier, which does not contribute to the transfer of data. With a complex modulating signal such as voice, video, or music, the sidebands generally contain 20 to 25 percent of the overall signal power; thus the carrier consumes 75 to 80 percent of the power. This makes AM an inefficient mode. If an attempt is made to increase the

modulating data input amplitude beyond these limits, the signal will become distorted, and will occupy a much greater **bandwidth** than it should. This is called *overmodulation*, and can result in interference to signals on nearby frequencies.

AMPS

See "Advanced Mobile Phone Service"

AMR

AMR (Audio/Modem Riser) is a specification developed by Intel for packaging the **analog I/O audio** functions of **modem** circuitry together with a **codec** chip (which converts back and forth from analog to digital) on a small board that plugs directly into a computer's **motherboard**. The small board is called a *riser* because it rises above the motherboard rather than laying flatly on it. Having this circuitry on a riser means that it doesn't have to be part of the motherboard itself. Because getting certification for the manufacture of a new motherboard design is a lengthy process, removing this function from the motherboard provides more flexibility for manufacturers and allows advances in audio modem design to be implemented more easily. Another specification, MDC (Mobile Daughter Card) is the equivalent of AMR but for use in mobile computers.

In the past, an internal modem was installed in one of several **slots** inside the computer **chassis** and an external modem was plugged into a serial port at the rear of the computer. With AMR design, the slot can now be used for other purposes. The AMR card can also provide the foundation for higher-quality audio solutions such as 3D positional audio and better **MIDI** music production.

AMR slot

See "AMR"

anacronym

An anacronym is an **acronym** or an abbreviation so old or familiar that no one remembers what its letters stand for. By the way, an "acronym" is not just any abbreviation. It's a word that is short for other words, usually using their initial letters. An abbreviation formed of letters that don't form a word is sometimes known as an "initialism." Our Webster's cites "snafu" and "radar" as examples of acronyms. (Good examples of anacronyms, too!) But "snafu" and "**radar**" seem like acronyms that have passed into general usage (notice the all lowercase). Most of today's acronyms are still all uppercase; only a few will ever become generic. An example of an acronym that probably won't become lower-cased is **WINS** (Windows Internet Naming Service). "IBM" is an initialism, not an acronym. So are "**MPEG**" (Moving Picture Experts Group) and "**EPROM**" (erasable programmable read-only memory).

The Webster's definition does raise a question (and begs one, too). Is the "word" an acronym forms a real, already existing word, or intended to be accepted as a new "word," or just something easily pronounceable? If the first case, then "snafu" and "radar" really aren't acronyms. If the second or third case, they are. However, since any initialism can be thought of as a word and certainly has to be pronounceable so you can say it out loud, one could argue that any initialism is an acronym. We don't think anyone has looked at this issue squarely (and we're not planning to ourselves, but just wanted to demonstrate the ambiguous kind of world we live in...which is why most people frankly don't care whether an acronym is a word or not).

But getting back to anacronyms, they seem to be forming at an alarming rate. Do you remember what this mixture of acronyms and initialisms stand for?

analog

Analog technology refers to electronic transmission accomplished by adding signals of varying frequency or amplitude to carrier waves of a given frequency of alternating electromagnetic current. Broadcast and phone transmission have conventionally used analog technology.

Analog also connotes any fluctuating, evolving, or continually changing process. Analog is usually represented as a series of sine waves. The term originated because the modulation of the carrier wave is analogous to the fluctuations of the voice itself.

A **modem** is used to convert the digital information in your computer to analog signals for your phone line and to convert analog phone signals to digital information for your computer.

analog computing

Analog computing is a term used by Paul Saffo of the Institute for the Future in Palo Alto, California, to describe silicon-based microsensors that sense and react to external (natural) stimuli in something that approximates the rhythm of reality rather than the “artificial” binary behavior of digital computing. Saffo foresees that, by implanting tiny machines including sensors and actuators in the same materials used to manufacture digital memory and processors (and by using some of the same manufacturing techniques), the next decade will increasingly find uses for “intelligent” material that responds to its environment in **analog** or dynamically responding fashion. Examples include packages that can “talk back” to their handlers; airplane wings that can reshape themselves as they meet turbulence; chairs that can mold themselves into the best supporting shape for each person.

Saffo’s analog computers also go by the names of **MEMS** (micro-electromechanical systems) and **smart matter**.

Analog Display Services Interface

See “ADSI”

analog-to-digital conversion

Analog-to-digital conversion is an electronic process in which a continuously variable (**analog**) signal is changed, without altering its essential content, into a multi-level (**digital**) signal.

The input to an *analog-to-digital converter* (ADC) consists of a **voltage** that varies among a theoretically infinite number of values. Examples are sine waves, the waveforms representing human speech, and the signals from a conventional television camera. The output of the ADC, in contrast, has defined levels or states. The number of states is almost always a power of two—that is, 2, 4, 8, 16, etc. The simplest digital signals have only two states, and are called **binary**. All whole numbers can be represented in binary form as strings of ones and zeros.

Digital signals propagate more efficiently than analog signals, largely because digital impulses, which are well-defined and orderly, are easier for electronic circuits to distinguish from noise, which is chaotic. This is the chief advantage of digital modes in communications. Computers

“talk” and “think” in terms of binary digital data; while a **microprocessor** can analyze analog data, it must be converted into digital form for the computer to make sense of it.

A typical telephone **modem** makes use of an ADC to convert the incoming audio from a twisted-pair line into signals the computer can understand. In a **digital signal processing** system, an ADC is required if the signal input is analog.

analytical CRM

See “CRM analytics”

Analytical Engine

The Analytical Engine was, or would have been, the world’s first general-purpose computer. Designed in the 1830s by the English mathematician and inventor **Charles Babbage**, the Analytical Engine introduced a number of computing concepts still in use today. Features included a store and mill, analogous to today’s **memory** and **processor**. Input and output was provided using punched cards, based on the invention by Jacquard in the early 1800s.

Babbage began his work on the Analytical Engine in 1834. He envisaged the computer to be constructed with brass fittings and powered by steam. It was never built, since the government of the day was unwilling to fund its construction, having already sunk 17,000 English pounds into Babbage’s fruitless project to build an earlier invention, the **Difference Engine**.

Babbage was assisted in his endeavours by Ada Augusta, Countess of Lovelace (and daughter of the poet Byron) who is regarded as the world’s first computer programmer for her work with Babbage. She developed a punched card program to calculate the Bernoulli numbers.

While Babbage’s earlier Difference Engine was finally constructed in 1991, his Analytical Engine remains unrealized. As the originator of several important concepts in computing, however, Babbage’s place in history is secure.

analytics

See “CRM analytics”

anchor

In Hypertext Markup Language (**HTML**), an anchor is the establishing of a term, phrase, image, or other information object as being either:

- The target of a **hypertext link** within a document, or
- A reference (a link you can select) to such a target

Note that any HTML file name is automatically an anchor or target that can be linked to. An anchor WITHIN a file to which you can link directly is identified by the # sign followed by the name.

AND

See “logic gate”

Andrew

Andrew was a joint project between Carnegie-Mellon University and IBM to set up a distributed computing environment on the CMU campus. It was designed to serve 4,000 UNIX workstations. The project was named for Andrew Carnegie and Andrew Mellon. One result of Andrew was the **Andrew file system**.

Andrew file system

An **Andrew** file system (AFS) is a location-independent file system that uses a local cache to reduce the workload and increase the performance of a distributed computing environment. A first request for data to a server from a workstation is satisfied by the server and placed in a local cache. A second request for the same data is satisfied from the local cache.

The Andrew file system was developed at Carnegie-Mellon University.

ANI

ANI (Automatic Number Identification) is a service that provides the receiver of a telephone call with the number of the calling phone. The method of providing this information is determined by the service provider (such as AT&T, MCI, Sprint, and so forth). The service is often provided by sending the digital tone multi frequency (DTMF) tones along with the call. Home users of ANI can screen callers. **Call centers** can use the information to forward calls to different people for different geographic areas. It is commonly used by emergency center dispatchers to save the caller having to report the information and, when necessary, to help locate callers. A telephone company's 9-1-1 service to a public safety point usually includes the ANI feature.

animated GIF

An animated GIF (**Graphics Interchange Format**) file is a graphic image on a Web page that moves—for example, a twirling icon or a banner with a hand that waves or letters that magically get larger. In particular, an animated GIF is a file in the Graphics Interchange Format specified as **GIF89a** that contains within the single file a set of images that are presented in a specified order. An animated GIF can loop endlessly (and it appears as though your document never finishes arriving) or it can present one or a few sequences and then stop the animation. Animated GIFs are frequently used in Web ad **banners**.

Java, **Flash**, and other tools can be used to achieve the same effects as an animated GIF. However, animated GIFs are generally easier to create than comparable images with Java or Flash and usually smaller in size and thus faster to display.

anime

Anime (pronounced AH-nee-may) is a term for a style of Japanese comic book and video cartoon animation in which the main characters have large doe-like eyes. Many Web sites are devoted to anime. Anime is the prevalent style in Japanese comic books or *manga*. In Japan, the comic book is a popular form of entertainment for adults as well as for younger audiences. Story lines are often very sophisticated and complex and extend into episodic series. Typical anime themes or genres include Ninja and other martial arts; the supernatural or horror story; the romance; and science fiction including robots and space ships. Foils for the main characters, including robots, monsters, or just plain bad people, often lack the doe-eyed quality.

Variations of anime called *hentai* and *ecchai* are sexually-oriented. *Doujinshi* is the term for “autonomous comics,” or comics written and distributed by independent and often amateur devotees of anime.

anonymous e-mail

Anonymous e-mail is e-mail that has been directed to a recipient through a third-party server that does not identify the originator of the message.

anonymous FTP

Using the Internet's File Transfer Protocol (FTP), anonymous FTP is a method for giving users access to files so that they don't need to identify themselves to the server. Using an FTP program or the FTP command interface, the user enters “anonymous” as a user ID. Usually, the password is defaulted or furnished by the FTP server. Anonymous FTP is a common way to get access to a server in order to view or download files that are publicly available.

If someone tells you to use anonymous FTP and gives you the server name, just remember to use the word “anonymous” for your user ID. Usually, you can enter anything as a password.

ANSI

ANSI (American National Standards Institute) is the primary organization for fostering the development of technology standards in the United States. ANSI works with industry groups and is the U.S. member of the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC).

Long-established computer standards from ANSI include the American Standard Code for Information Interchange (ASCII) and the Small Computer System Interface (SCSI).

antenna

An antenna is a specialized **transducer** that converts **RF** (radio-frequency) fields into **AC** (alternating current) or vice-versa. There are two basic types: the receiving antenna, which intercepts RF energy and delivers AC to electronic equipment, and the transmitting antenna, which is fed with AC from electronic equipment and generates an RF field.

In computer and Internet **wireless** applications, the most common type of antenna is the *dish*, used for **satellite** communications. Dish antennas are generally practical only at microwave frequencies (above approximately 3 **GHz**). The dish consists of a paraboloidal or spherical reflector with an active element at its focus. When used for receiving, the dish collects RF from a distant source and focuses it at the active element. When used for transmitting, the active element radiates RF that is collimated by the reflector for delivery in a specific direction.

At frequencies below 3 GHz, many different types of antennas are used. The simplest is a length of wire, connected at one end to a transmitter or receiver. More often, the radiating/receiving element is placed at a distance from the transmitter or receiver, and AC is delivered to or from the antenna by means of an RF transmission line, also called a *feed line* or *feeder*.

anthropomorphism

Anthropomorphism is the tendency for people to think of inanimate objects as having human-like characteristics. If you have ever named your car, talked to your computer or begged your printer to work, you are guilty of assigning anthropomorphic characteristics to a machine. In recent years, artificial intelligence (**AI**) has progressed to the point that computers can learn from their mistakes so that they do not make a specific error more than once. The ability to self-correct, combined with the ability programmers have to enable speech synthesizers to produce responses that seem emotional, makes **robots** and other interactive devices seem more human-like than ever.

antialiasing

Antialiasing is the smoothing of the image or sound roughness caused by **aliasing**. With images, approaches include adjusting pixel positions or setting pixel intensities so that there is a more gradual transition between the color of a line and the background color. With sound, aliases are removed by eliminating frequencies above half the sampling frequencies.

antidisintermediation

In commerce, antidisintermediation is a term used to describe the preservation of intermediary positions. Today's consumer can access goods or information on the Internet that traditionally required the assistance of an intermediary such as a retailer, travel agent, or banker. By cutting out the middleman (**disintermediation**), e-businesses are able to sell goods and services more quickly and efficiently, and for lower prices.

Antidisintermediation measures are carried out through business incentives (or disincentives) and legal actions to ensure that intermediary positions are not eliminated. Since a good deal of profit is made by individuals or businesses serving as intermediaries between the primary source of a good or service and the consumer, intermediaries are using antidisintermediation measures to re-establish their niche in the changing economy.

In one example of antidisintermediation (cited in "The death of "e" and the Birth of the Real New Economy: Business Models, Technologies and Strategies for the 21st Century" by Peter Fingar and Ronald Aronica), Home Depot sent a letter to 1,000 of its suppliers (including Black & Decker and General Electric, for example) warning them that the company would be less likely to do business with those among them who also marketed their goods online.

antiferromagnetically-coupled media

See "pixie dust"

Antigen

1) Sybari's Antigen is **antivirus software** for Lotus Domino and Microsoft Exchange.

2) AntiGen (with a capital G) is freeware developed by Fresh Software to detect the presence of **Back Orifice** on a machine running Microsoft Windows. AntiGen removes Back Orifice and cleans up system changes that have been made, using a wizard interface. According to Fresh Software, AntiGen was the first application to offer protection from Back Orifice in 1998.

These product names are apparently derived from the biological term, antigen, which is a foreign substance in the body that stimulates the production of an antibody (which fights disease).

anti-replay protocol

The anti-replay protocol is part of the Internet Engineering Task Force (**IETF**) Internet Protocol Security (**IPSec**) standard. Anti-replay ensures IP **packet**-level security by making it impossible for a hacker to intercept message packets and insert changed packets into the data stream between a source computer and a destination computer. By detecting packets that match the sequence numbers of those

#

I

J

K

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

that have already arrived, the anti-replay mechanism helps to ensure that invalid packets are discarded. Both of the main protocols in the IPSec standard, the Encapsulating Security Payload (ESP) and the Authentication Header (AH), use anti-replay protection.

The anti-replay mechanism works by keeping track of the sequence numbers in packets as they arrive. Whether the mechanism is used at the receiving end depends upon a security level setting set by the receiver. When a security association has been established between a sender and a receiver, their counters are initialized at zero. The first packet sent will have a sequence number of 1, the second 2, and so on. Each time a packet is sent, the receiver verifies that the number is not that of a previously sent packet. When detection of a replayed packet occurs, the program sends an error message, discards the replayed packet, and logs the event—including in the log entry identifiers such as the date/time received, source address, destination address, and the sequence number.

antivirus software

Antivirus (or “anti-virus”) software is a class of program that searches your hard drive and floppy disks for any known or potential viruses. The market for this kind of program has expanded because of Internet growth and the increasing use of the Internet by businesses concerned about protecting their computer assets.

any key

The phrase “any key,” which frequently appears in the direction to computer users to “Press any key,” is reportedly a source of confusion to many. At least one help desk person reports that users sometimes examine that direction more carefully than intended and call to find out whether “any key” includes such keys as the tilde, the Break key, and the key on many keyboards that shows the Microsoft Windows logo.

“Any key” does indeed include those keys.

anycast

In Internet Protocol Version 6 (IPv6), anycast is communication between a single sender and the nearest of several receivers in a group. The term exists in contradistinction to **multicast**, communication between a single sender and multiple receivers, and **unicast**, communication between a single sender and a single receiver in a network.

Anycasting is designed to let one host initiate the efficient updating of **router** tables for a group of hosts. IPv6 can determine which gateway host is closest and sends the packets to that host as though it were a **unicast** communication. In turn, that host can anycast to another host in the group until all routing tables are updated.

AOP

See “aspect-oriented programming”

Apache

Apache is a freely available Web **server** that is distributed under an “open source” license. Version 2.0 runs on most UNIX-based operating systems (such as **Linux**, **Solaris**, Digital UNIX, and **AIX**), on other UNIX/POSIX-derived systems (such as Rhapsody, **BeOS**, and BS2000/OSD), on AmigaOS, and on **Windows 2000**. According to the Netcraft (www.netcraft.com) Web server survey in February, 2001, 60% of all Web sites on the Internet are using Apache (62% including Apache derivatives), making Apache more widely used than all other Web servers combined.

Apache complies with the newest level of the Hypertext Transport Protocol, **HTTP 1.1**. Free support is provided through a bug reporting system and several **Usernet** newsgroups. Several companies offer priced support.

APAR

See “authorized program analysis report”

API

See “application program interface”

APL

APL (A Programming Language) is a general-purpose, third-generation (3GL) programming language that allows certain data manipulations to be expressed with a special non-ASCII set of symbols, resulting in programs that are shorter than would be possible using most other languages. APL’s notation allows **matrix** manipulation as well as **recursion** functions to be built into simple expressions rather than requiring multiple language statements. APL is more frequently thought of as a language for scientific computation, but it can be used for other purposes as well. Programs can be developed interactively and are usually **interpreted** rather than compiled. The special symbols require keyboard support and specific editors so that the symbols can be displayed and printed.

A-Plus

See “A+”

apogee

When a satellite follows a non-circular orbit around the earth, the satellite’s path is an ellipse with the center of the earth at one focus. Such a satellite has variable altitude and variable orbital speed. The point of highest altitude is called apogee. The term also applies to the maximum distance in kilometers or miles between the satellite and the center of

the earth. (Apogee can be measured between the satellite and the earth's surface, although this is a less precise specification because the earth is not a perfect sphere. The difference is approximately 4,000 miles or 6,400 kilometers.)

At apogee, a satellite travels more slowly than at any other point in its orbit. When viewed from the earth's surface, a satellite at or near apogee takes a long time to traverse the sky. In communications, apogee is the best time to access a satellite. Although its distance means that the signal path is long, the fact that the satellite is slowly moving means that it is accessible for a comparatively long time. In addition, if a directional antenna is used at a ground-based station, it is relatively easy to track the satellite because the position of the antenna (azimuth and elevation) need not be adjusted very often or rapidly.

One of the principal advantages of a geostationary satellite is the fact that it follows a circular orbit, so the orbital speed is constant. In addition, the satellite's synchronization with the earth's orbit means that the antenna of an earth-based station can be pointed at a fixed spot in the sky, and no further adjustment of antenna orientation is needed.

Compare **perigee**.

apparent power

Apparent power is a measure of alternating current (AC) power that is computed by multiplying the root-mean-square (rms) current by the root-mean-square voltage. In a direct current (DC) circuit, or in an AC circuit whose **impedance** is a pure **resistance**, the voltage and current are in phase, and the following formula holds:

$$P = E_{\text{rms}}I_{\text{rms}}$$

where P is the power in watts, E_{rms} is the **root-mean-square** (rms) voltage in volts, and I_{rms} is the rms current in amperes. But in an AC circuit whose impedance consists of reactance as well as resistance, the voltage and current are not in phase. This complicates the determination of **power**.

In an AC circuit, the product of the rms voltage and the rms current is called **apparent power**. When the impedance is a pure resistance, the apparent power is the same as the **true power**. But when reactance exists, the apparent power is greater than the true power. The vector difference between the apparent and true power is called **reactive power**.

If P_a represents the apparent power in a complex AC circuit, P_t represents the true power, and P_r represents the reactive power, then the following equation holds:

$$P_a^2 = P_t^2 + P_r^2$$

APPC

APPC (Advanced Program-to-Program Communication, sometimes called LU 6.2) is a communication **protocol** and programming interface standard that operates in the **presentation layer** (the layer that ensures that messages are in the proper format for the recipient) and the **session layer** (the layer responsible for setting up and taking down the association of the two end points in a connection) of the Open Systems Interconnection (OSI) communications model. Originally developed by IBM as a remote **transaction** processing tool, APPC is now used to provide **distributed** services within a **heterogeneous** computing environment.

APPC software enables high-speed communication to take place between programs residing on different computers, and between workstations and **midrange** and **mainframe** computer servers. APPC is an **open** standard that is supported on most platforms.

APPC is based on IBM's Systems Network Architecture (SNA).

Apple attachment unit interface

See "AAUI"

Appleshare

The AppleShare protocol is a communications **protocol** from Apple Computer that allows **client** applications in a computer to exchange **files** with and request services from **server** programs in a computer network. AppleShare can be used over the Internet on top of the **TCP/IP** protocol, or on top of other network protocols such as **Internetwork Packet Exchange** and **AppleTalk**. Using the AppleShare protocol, a user can access files, applications, printers, and other resources on a remote server. It can communicate with any server program that is set up to receive an AppleShare client request.

All Macintosh and **Mac OS** clones include client and server AppleShare protocol support. Microsoft **Windows NT** Server and Novell **NetWare** both provide AppleShare server protocol support, although they currently only support AppleShare over AppleTalk. Third-party AppleShare client/

server support is available for Microsoft Windows for Workgroups, Windows 95, and Windows NT, as well as for UNIX systems.

A given client and server may implement different sets of AppleShare protocol variations. The set of protocols to be used is negotiated before starting a session.

applet

An applet is a little **application**. Prior to the World Wide Web, the built-in writing and drawing programs that came with Windows were sometimes called "applets." On the Web, using **Java**, the **object-oriented programming** language, an applet is a small program that can be sent along with a Web page to a user. Java applets can perform interactive animations, immediate calculations, or other simple tasks without having to send a user request back to the server.

AppleTalk

AppleTalk is a set of local area network communication **protocols** originally created for Apple computers. An AppleTalk network can support up to 32 devices and data can be exchanged at a speed of 230.4 kilobits per second (Kbps). Devices can be as much as 1,000 feet apart. AppleTalk's Datagram Delivery Protocol corresponds closely to the **Network layer** of the Open Systems Interconnection (OSI) communication model.

AppleTalk Address Resolution Protocol

See "ARP"

appliance

An appliance or "network appliance" is a term used to denote a relatively low-cost PC designed for Internet access and specialized business use, but without the capabilities of a fully-equipped PC.

application

1) In information technology, an application is the use of a technology, system, or product.

2) The term *application* is a shorter form of **application program**. An application program is a **program** designed to perform a specific function directly for the user or, in some cases, for another application program. Examples of applications include word processors, database programs, Web browsers, development tools, drawing, paint, image editing programs, and communication programs. Applications use the services of the computer's **operating system** and other supporting applications. The formal requests and means of communicating with other programs that an application program uses is called the application program interface (API).

application integration

Application integration is the process of bringing **data** or a function from one **application** program together with that of another application program. **Object-oriented programming** technology makes application integration easier to achieve. With traditional procedural programming, "bridge" programs had to be written so that one program could work with data or the output from functions in another program. The introduction of program "objects" such as Windows **OCX** and **ActiveX controls** provide standard interfaces so that objects designed for use in one application can be reused in other applications. Some software houses have developed programs that exploit this object technology so that you can have data or functions (object components or "controls") from one application (such as a word processor) be recognized by another application (such as a spreadsheet program).

The result of integration may be a new application with its own user interface or the capability of a desktop or mainframe application to handle data and include capabilities borrowed from other applications.

Application layer

In the Open Systems Interconnection (OSI) communications model, the Application layer provides services for **application programs** that ensure that communication is possible. The Application layer is NOT the application itself that is doing the communication. It is a service layer that provides these services:

- Makes sure that the other party is identified and can be reached
- If appropriate, authenticates either the message sender or receiver or both
- Makes sure that necessary communication resources exist (for example, is there a modem in the sender's computer?)
- Ensures agreement at both ends about error recovery procedures, data integrity, and privacy
- Determines protocol and data syntax rules at the application level. It may be convenient to think of the Application layer as the high-level set-up services for the application program or an interactive user.

application program

An application program (sometimes shortened to **application**) is any **program** designed to perform a specific function directly for the user or, in some cases, for another application program. Examples of application programs include word processors; database programs; Web browsers; development tools; drawing, paint, and image editing programs; and communication programs. Application programs use the services of the computer's **operating**

system and other supporting programs. The formal requests for services and means of communicating with other programs that a programmer uses in writing an application program is called the application program interface (**API**).

application program interface

An application program interface (**API**—and sometimes spelled *application programming interface*) is the specific method prescribed by a computer **operating system** or by an **application program** by which a programmer writing an application program can make requests of the operating system or another application.

An **API** can be contrasted with a **graphical user interface** or a *command interface* (both of which are direct *user interfaces*) as interfaces to an operating system or a program.

application server

An application server is a **server** program in a computer in a **distributed network** that provides the business logic for an application program. The application server is frequently viewed as part of a **three-tier application**, consisting of a graphical user interface (**GUI**) server, an application (business logic) server, and a **database** and **transaction** server. More descriptively, it can be viewed as dividing an application into:

1. A first-tier, **front-end**, Web browser-based graphical user interface, usually at a personal computer or workstation
2. A middle-tier business logic application or set of applications, possibly on a local area network or intranet server
3. A third-tier, **back-end**, database and transaction server, sometimes on a mainframe or large server

Older, **legacy application** databases and transaction management applications are part of the back end or third tier. The application server is the middleman between browser-based front-ends and back-end databases and legacy systems.

In many usages, the application server combines or works with a Web (**Hypertext Transfer Protocol**) server and is called a *Web application server*. The Web browser supports an easy-to-create HTML-based front-end for the user. The Web server provides several different ways to forward a request to an application server and to forward back a modified or new Web page to the user. These approaches include the Common Gateway Interface (**CGI**), **FastCGI**, Microsoft's **Active Server Page**, and the **Java Server Page**. In some cases, the Web application servers also support request "brokering" interfaces such as **CORBA** Internet Inter-ORB Protocol (**IIOP**).

application service provider

ASP is also an abbreviation for **Active Server Page**.

An application service provider (**ASP**) is a company that offers individuals or enterprises access over the Internet to applications and related services that would otherwise have to be located in their own personal or enterprise computers. Sometimes referred to as "apps-on-tap," **ASP** services are expected to become an important alternative, not only for smaller companies with low budgets for information technology, but also for larger companies as a form of **outsourcing** and for many services for individuals as well. Early applications include:

- **Remote access** serving for the users of an enterprise
- An off-premises local area network to which mobile users can be connected, with a common file server
- Specialized applications that would be expensive to install and maintain within your own company or on your own computer

Hewlett-Packard, **SAP**, and **Qwest** have formed one of the first major alliances for providing **ASP** services. They plan to make **SAP**'s popular **R/3** applications available at "cybercenters" that will serve the applications to other companies. Microsoft is allowing some companies to offer its **BackOffice** products, including **SQL Server**, **Exchange** and **Windows NT Server** on a rental, pay-as-you-use basis.

While **ASPs** are forecast to provide applications and services to small enterprises and individuals on a pay-per-use or yearly license basis, larger corporations are essentially providing their own **ASP** service in-house, moving applications off personal computers and putting them on a special kind of **application server** that is designed to handle the stripped-down kind of **thin client** workstation. This allows an enterprise to reassert the central control over application cost and usage that corporations formerly had in the period prior to the advent of the PC. Microsoft's **Terminal Server** product and Citrix's **WinFrame** products are leading thin-client application server products.

Application Service Provider Industry Consortium

idiomatic expression for “available.”) The businesses that furnish apps-on-tap are called **application service providers**. The use of apps-on-tap is a form of **outsourcing**.

aptent

Aptent (pronounced AP-tehnt, compounded from ‘application’ and ‘content’) is the combination of computer program applications with textual and graphic content on the Internet. The term was used by Tim Miller in an article on the subject in *The Industry Standard* magazine. Aptent, Miller observes, is increasingly what makes Web enterprises successful since it blends the capabilities of the computer and networking with the Web’s amazing capacity to amass content. Aptent is sometimes mostly programming, sometimes mostly content. Content is made available in new ways, arriving with programs that can interact with users, interpret and react to user behavior, send agents in search of content to be provided later, explode into more detailed content, allow users to develop their own content, and so forth. Advertisers and marketers, interested in ads and ideas that engage and involve, are also embracing aptent. Miller identifies some classes of aptent as:

Search engines and directories. The original aptent providers, Yahoo, Excite, Lycos, Infoseek, and others scour the Web’s content and digest and index it so that users can access its millions of pages.

Communications aptent. E-mail and chat and discussion group sites and programming provide new ways for content to be created and exchanged. Important companies in communications aptent are Hotmail, WebChat Broadcasting, Parachat, Mirabilis, Silicon Investor, and Go2Net.

“Squirrel” aptent. Providing space where users can create their own personal home pages, address books, and special-event calendars, companies like GeoCities have brought users actively to the Web as full-time participants or at least allowed them to view the Web as a place to store their own content. Tripod and WhoWhere are other sites that let users create their own content.

Agent or “bot” aptent. These sites or applications allow users to gather information tailored to individual needs, compare prices at different online stores, and even discover or “mine” information that matches a user’s profile. Jungle, C2B, Quando, and Computer ESP are product examples.

Companies or Web sites that provide aptent rather than mere content tend to “scale” in terms of potential revenue and are attractive to angels, venture capitalists, and investors. Some aptent is able to self-proliferate, users spreading it to other users, a kind of **viral marketing**.

Aptent, Miller concludes, is still in its infancy. The message, he says, is “about doing things, not reading things.”

arachniography

An arachniography (pronounced uh-RAK-nee-AH-gruf-ee) is a bibliography of Web pages. The term was coined by Andrew J. Butrica of NASA who first considered “webography” but didn’t like the mixing of word origins. He asked his brother, James, who teaches Classics at Memorial University, for a classical language equivalent of “web.” In Greek, *arachne* means both the spider and its web. So, for his history of NASA’s X-33 project, Andrew called his annotated list of Web pages an annotated arachniography. Since the Web is not a “biblio,” this particular **neologism** would seem to be useful.

The term has not yet been widely used, but it’s still early in the history of the Web. Meanwhile, if you are including Web sites in a bibliography for an academic or other formal paper or printed work, the Style Guide of the Modern Language Association (MLA) tells how to write a citation. The MLA guideline includes a number of examples of citations for use as models. For a Web site that is a scholarly project, they offer this model:

Victorian Women Writers Project. Ed. Perry Willett.

Apr. 1997. Indiana U. 26 Apr. 1997

<<http://www.indiana.edu/~letrs/vwwp/>>.

A drawback in the MLA’s Web citation style is that, if the **Uniform Resource Locator** and its angular brackets are transferred to a Web page, the URL will no longer be visible when viewed on a browser. This is because Web browsers view the information within a matched pair of angular brackets as an HTML tag and therefore not to be displayed. When creating the URL part of a citation, we recommend enclosing it within parentheses instead of angular brackets.

arachnotaxis

Arachnotaxis is the use of a table or structured list of URLs for Web sites (or words that hyperlink to Web sites) in order to help locate them. A structured **bookmark** list or a **portal directory** (such as the ones at Yahoo.com or SearchITServices.com) exemplify arachnotaxis, a term derived from Arachne, the weaver who in Greek legend was turned into a spider, and thence *arachnion*, a variation that meant the spider’s web, and *taxis*, a Greek word for an orderly or systematic arrangement of items or terms, especially by classification.

As a term, arachnotaxis could be considered a “serious” **sniglet** (a meaning in search of a term) until such time as its use is more widely adopted. Its inventor, Steve Gruenwald, first used the term in mid-1998, when he was searching for something to describe a taxonomy used to guide users to Web sites. (TechTarget.com sites use the term *taxonomy* to describe our categorized lists of Web sites.)

Also see **arachniography**, an independently-coined synonym.

Archie

Archie is a program that allows you to search the files of all the Internet **FTP servers** that offer **anonymous FTP**. Archie is actually an indexing **spider** that visits each anonymous FTP site, reads all the **directory** and **file** names, and then indexes them in one large index. A user can then query Archie, which checks the query against its index. To use Archie, you can **Telnet** to a server that you know has Archie on it and then enter Archie search commands. However, it's easier to use a forms interface on the Web called ArchiePlex.

Archie has become less important with the growth of the World Wide Web. It is perhaps of most use for serious researchers who have already tried the Web's main search engines first or who already know that the topic of their search is likely to be found on FTP servers.

architecture

In information technology, especially computers and more recently networks, architecture is a term applied to both the process and the outcome of thinking out and specifying the overall structure, logical components, and the logical interrelationships of a **computer**, its **operating system**, a **network**, or other conception. An architecture can be a *reference model*, such as the Open Systems Interconnection (**OSI**) reference model, intended as a model for specific product architectures or it can be a specific product architecture, such as that for an Intel **Pentium microprocessor** or for IBM's OS/390 operating system.

Computer architecture can be divided into five fundamental components: input/output, storage, communication, control, and processing. In practice, each of these components (sometimes called *subsystems*) is sometimes said to have an architecture, so, as usual, context contributes to usage and meaning.

By comparison, the term *design* connotes thinking that has less scope than architecture. An architecture is a design, but most designs are not architectures. A single **component** or a new **function** has a design that has to fit within the overall architecture.

A similar term, *framework*, can be thought of as the structural part of an architecture.

archive

1) An archive is a collection of computer **files** that have been packaged together for backup, to transport to some other location, for saving away from the computer so that more hard disk storage can be made available, or for some other purpose. An archive can include a simple list of files or files organized under a directory or catalog structure (depending on how a particular program supports archiving).

On personal computers with the Windows operating system, WinZip is a popular program that lets you create an archive (a single file that holds a number of files that you plan to

save to another medium or send someone electronically) or extract its files. WinZip also compresses the files that are archived, but compression is not required to create an archive. A WinZip archive has the file name suffix ".zip".

In **UNIX**-based operating systems, the **tar** (tape archive) utility can be used to create an archive or extract files from one. On **mainframe** operating systems such as IBM's MVS and OS/390, procedures for archiving or backing up files are often automated as a daily operation.

2) On Web sites as well as in libraries, an archive is a collection of individual publications that are often cataloged or listed and made accessible in some way. Magazines, journals, and newspapers with Web sites sometimes refer to their back issues as an archive.

3) Web and **File Transfer Protocol** sites that provide software programs that can be downloaded sometimes refer to the list of downloadable files as an archive or as archives.

ARCNET

ARCNET is a widely-installed local area network (**LAN**) technology that uses a *token-bus* scheme for managing line sharing among the workstations and other devices connected on the LAN. The LAN server continuously circulates empty message frames on a **bus** (a line in which every message goes through every device on the line and a device uses only those with its address). When a device wants to send a message, it inserts a "token" (this can be as simple as setting a token bit to 1) in an empty frame in which it also inserts the message. When the destination device or LAN server reads the message, it resets the token to 0 so that the frame can be reused by any other device. The scheme is very efficient when traffic increases since all devices are afforded the same opportunity to use the shared network.

ARCNET can use **coaxial cable** or **fiber optic** lines. ARCNET is one of four major LAN technologies, which also include **Ethernet**, **token ring**, and **DDI**.

area

Area (symbolized *A*) is a two-dimensional quantity representing amount or extent of surface. The standard unit of area in the International System of Units (**SI**) is the **meter squared** (m²).

Area is usually measured or defined on a flat surface, also called a Euclidean plane, or on a spherical surface. For example, we might speak of the area of a parcel of land, the cross-sectional area of a **fiber optic** cable, or the surface area of the earth. However, surface area is occasionally determined for irregular or complex objects. In the case of certain extremely complex or esoteric surfaces, the area might be impossible to define or measure. One example is a mathematical object having a fractional number of dimensions. Another example is an object without a well-defined surface.

When expressing large or small areas, **prefix multipliers** are attached to the meter squared. The table below shows the most common alternative displacement units and their relationship to the meter squared.

Unit (and symbol)	To convert to meters squared, multiply by:	Conversely, multiply by:
kilometer squared (km ²)	10 ⁶	10 ⁻⁶
centimeter (cm ²)	10 ⁻⁴	10 ⁴
millimeter (mm ²)	10 ⁻⁶	10 ⁶
circular mil foot squared (ft ²)	5.06 × 10 ⁻¹⁰ 0.0929	1.97 × 10 ⁹ 10.76
micrometer squared or micron squared (μ ²)	10 ⁻¹²	10 ¹²
nanometer squared (nm ²)	10 ⁻¹⁸	10 ¹⁸
Angström squared (Å ²)	10 ⁻²⁰	10 ²⁰

Compare **displacement**, and **volume**.

Also see **centimeter**, **meter**, **meter squared**, **meter cubed**, and International System of Units (SI).

area code

In the North American telephone system, an area code is a three-digit code delineating a “toll” area in the United States, Canada, and Mexico. Area codes are distributed according to the North American Number Plan (NANP). The area code is also referred to as a Number Plan Area or NPA.

ARIN

See “American Registry of Internet Numbers”

arithmetic-logic unit

An arithmetic-logic unit (ALU) is the part of a computer **processor** (CPU) that carries out arithmetic and logic operations on the **operands** in computer **instruction words**. In some processors, the ALU is divided into two units, an arithmetic unit (AU) and a logic unit (LU). Some processors contain more than one AU—for example, one for *fixed-point* operations and another for *floating-point* operations. (In personal computers floating point operations are sometimes done by a **floating point unit** on a separate chip called a numeric coprocessor.)

Typically, the ALU has direct input and output access to the processor controller, main memory (random access memory or **RAM** in a personal computer), and input/output devices. Inputs and outputs flow along an electronic path that is called a **bus**. The input consists of an instruction word (sometimes called a machine instruction word) that contains

an operation code (sometimes called an “op code”), one or more operands, and sometimes a format code. The operation code tells the ALU what operation to perform and the operands are used in the operation. (For example, two operands might be added together or compared logically.) The format may be combined with the op code and tells, for example, whether this is a fixed-point or a floating-point instruction. The output consists of a result that is placed in a storage *register* and settings that indicate whether the operation was performed successfully. (If it isn't, some sort of status will be stored in a permanent place that is sometimes called the machine status word.)

In general, the ALU includes storage places for input operands, operands that are being added, the accumulated result (stored in an *accumulator*), and shifted results. The flow of bits and the operations performed on them in the subunits of the ALU is controlled by gated circuits. The gates in these circuits are controlled by a sequence logic unit that uses a particular **algorithm** or sequence for each operation code. In the arithmetic unit, multiplication and division are done by a series of adding or subtracting and shifting operations. There are several ways to represent negative numbers. In the logic unit, one of 16 possible logic operations can be performed—such as comparing two operands and identifying where bits don't match.

The design of the ALU is obviously a critical part of the processor and new approaches to speeding up instruction handling are continually being developed.

ARJ

ARJ is an **archiving** program created by Robert Jung for IBM-compatible computers. The letters stand for “Archive Robert Jung.”

ARJ compresses files to save storage space and speed transmission when moved from one computer to another. The program has long filename support, file version management, archive merging, **password** protection, data damage protection, a **digital signature** option, recurse directory support, ANSI escape sequence display handler, configurable command options, handling of up to 99 volumes, ability to store up to 250 **backups** per archive, ability to work with duplicate filenames within archives, and archives that span diskettes.

There are two versions of ARJ currently available, called ARJ and ARJ32. ARJ runs in **DOS** (Disk Operating System) 2.11 and above, and requires only 512K of random-access memory (**RAM**). ARJ32 runs in 32-bit Windows 95 and later systems. Either version can work with files of up to 1 **gigabyte**, and can process a drive larger than 2 gigabytes with its multiple volume feature as long as any individual file is not larger than 1 GB. Both ARJ and ARJ32 are available in English, Portuguese, German, Polish, French, and Czech.

ARP

See “Address Resolution Protocol”

ARPA

An agency of the United States Department of Defense, ARPA (Advanced Research Projects Agency) underwrote the development of the Internet beginning in 1969. Known as **ARPANET**, it was designed so that, in case of war and the loss of any group of sites, remaining sites would still be able to communicate along alternate routes. No site would be critical to the operation of the network.

Eventually, ARPANET was divided into Milnet, which connected military sites, and a new ARPANET that connected other sites, mainly universities. A new communication protocol was developed, **TCP/IP**, so that all sites on either of the networks could communicate.

Additional networks came into being, all using the new protocol, TCP/IP, making possible the enormous number of interconnections that we have today.

ARPANET

ARPANET was the network that became the basis for the **Internet**. It was funded mainly by U.S. military sources and consisted of a number of individual computers connected by leased lines and using a packet-switching scheme.

ARPANET was replaced over time in the 1980’s by a separate new military network, the Defense Data Network, and NSFNet, a network of scientific and academic computers funded by the National Science Foundation. In 1995, NSFNet in turn began a phased withdrawal to turn what has become the *backbone* of the Internet (called vBNS) over to a consortium of commercial backbone providers (PSINet, UUNET, ANS/AOL, Sprint, MCI, and AGIS-Net99).

array

1) In general, an array is a number of items arranged in some specified way—for example, in a list or in a three-dimensional table.

2) In computer programming languages, an array is a group of objects with the same attributes that can be addressed individually, using such techniques as subscripting.

3) In random access memory (**RAM**), an array is the arrangement of memory cells.

artificial intellect

An artificial intellect (or “artilect”), according to Dr. Hugo de Garis, is a computer intelligence superior to that of humans in one or more spheres of knowledge together with an implicit will to use the intelligence. Artilects are the concern of artificial intelligence specialists (or “intelligists”) like de Garis, who speculates that human society may soon have to

face the question of whether and how we can restrain artificial intelligence from making decisions inimical to humans.

Dr. de Garis assumes that within one or two generations, we will have computers that are more sophisticated than human brains with the ability to experimentally evolve their intelligence into something much beyond what humans might contemplate or understand. de Garis wonders whether such machines would consider human beings important enough to preserve. He speculates that society will soon need to face the question of whether we should permit artilects to be built. He foresees two factions arising: the Cosmists, who argue that they should be built, and the Terras, believing that they should not. The Cosmists might believe that artilects would probably want to leave our planet to seek intelligences elsewhere in the universe. The Terras believe that it would be too dangerous for the human race to allow artilects to be developed.

artificial intelligence

See “AI”

AS/400

The AS/400—formally renamed the “eServer iSeries/400,” but still commonly known as AS/400—is a middle-size **server** designed for small businesses and departments in large enterprises and now redesigned so that it will work well in **distributed networks** with **Web applications**. The AS/400 uses the **PowerPC** microprocessor with its **reduced instruction set computer** technology. Its **operating system** is called the OS/400. With multi-**terabytes** of disk storage and a **Java virtual memory** closely tied into the operating system, IBM hopes to make the AS/400 a kind of versatile all-purpose server that can replace PC servers and Web servers in the world’s businesses, competing with both **Wintel** and **UNIX** servers, while giving its present enormous customer base an immediate leap into the Internet.

The AS/400, one of IBM’s greatest success stories, is widely installed in large enterprises at the department level, in small corporations, in government agencies, and in almost every industry segment. It succeeded another highly popular product, the System/36 and was itself based on a later, more sophisticated product, the System/38. AS/400 customers can choose from thousands of applications that have already been written and many have been “Web-enabled.” IBM points to the AS/400’s “uptime” of 99.9%.

The AS/400 comes with a **database** built-in. One widely-installed option is **Domino** (Notes with a Web browser).

According to IBM, these are some important new uses for the AS/400:

- **Data warehousing:** With multi-**gigabytes** of RAM and multi-terabytes of hard disk space, the AS/400 can be a repository for large amounts of company data to which **data mining** could be applied.

- **Java application development:** With its closely integrated Java virtual machine and new tools designed by IBM for building commercial applications with Java, the AS/400 can be used as a development system.
- **Web and e-commerce serving:** Equipped with a Web server and applications designed to support **e-commerce** (taking orders, tracking orders, providing service to customers, working with partners and suppliers) and with **firewall** capabilities, the AS/400 can handle Internet serving for a moderate-size company.
- **Corporate groupware services:** Assuming that Domino and Notes have been included with the system, it's designed to quickly provide a corporation with sophisticated e-mail, project file sharing, whiteboards, and electronic collaboration.

ASCII

ASCII (American Standard Code for Information Interchange) is the most common **format** for **text** files in computers and on the Internet. In an ASCII file, each alphabetic, numeric, or special character is represented with a 7-bit **binary** number (a string of seven 0s or 1s). 128 possible characters are defined.

UNIX and DOS-based operating systems use ASCII for text files. Windows NT and 2000 uses a newer code, **Unicode**. IBM's S/390 systems use a proprietary 8-bit code called **EBCDIC**. Conversion programs allow different operating systems to change a file from one code to another.

ASCII was developed by the American National Standards Institute (ANSI).

Asia Cellular Satellite System

Asia Cellular Satellite System (ACeS) is a combined **cellular telephone** and **satellite wireless** system from Ericsson that provides digital communication service to mobile phone and computer users in the Asia Pacific Region. Adding satellite communication to the terrestrial Global System for Mobile (**GSM**) communication system, ACeS is billed as the first integrated satellite-GSM system in the world. Users with Ericsson dual-mode terminals will be able to roam within the region switching as necessary between cellular (local) service and satellite service.

ACeS is expected to be available in an area from Indonesia in the South; Papua, New Guinea in the East; Japan in the North; and Pakistan in the West, an area with a combined population of three billion. ACeS will make it possible for many people to have telecommunication services for the first time. ACeS has signed over 19 **roaming service** agreements with GSM operators.

ACeS subscribers are provided with a GSM subscriber identify module (SIM) and a network access code (which is a telephone number) that can be used outside the region or within the region when blockage of satellite signals occur

(typically, by nearby buildings). GSM subscribers visiting the region can also reach other GSM services via satellite if they have an ACeS SIM and an ACeS terminal.

ASIC

An ASIC (application-specific integrated circuit) is a **microchip** designed for a special application, such as a particular kind of transmission protocol or a hand-held computer. You might contrast it with general integrated circuits, such as the microprocessor and the random access memory chips in your PC. ASICs are used in a wide-range of applications, including auto emission control, environmental monitoring, and personal digital assistants (**PDA**s).

An ASIC can be pre-manufactured for a special application or it can be custom manufactured (typically using components from a "building block" library of components) for a particular customer application.

Asimov's Three Laws of Robotics

Science-fiction author Isaac Asimov is often given credit for being the first person to use the term **robotics** in a short story composed in the 1940s. In the story, Asimov suggested three principles to guide the behavior of robots and smart machines. Asimov's Three Laws of Robotics, as they are called, have survived to the present:

1. Robots must never harm human beings.
2. Robots must follow instructions from humans without violating rule 1.
3. Robots must protect themselves without violating the other rules.

Also see **artificial intelligence**, **mechatronics**, **nanorobot**, and **robot**.

ASN.1

See "Abstract Syntax Notation One"

ASP

See "application service provider"

ASP.NET

See "ASP+"

ASP+

ASP+ (also called ASP.NET), is the next generation of Microsoft's Active Server Page (**ASP**), a feature of their Internet Information Server (**IIS**). Both ASP and ASP+ allow a Web site builder to dynamically build Web pages **on the fly** by inserting queries to a **relational database** in the Web page. ASP+ is different than its predecessor in two major ways: It supports code written in compiled languages such as **Visual Basic**, **C++**, **C#**, and **Perl**, and it features server

controls that can separate the code from the content, allowing **WYSIWYG** editing of pages. Although ASP+ is not **backwards compatible** with ASP, it is able to run side by side with ASP applications. ASP+ files can be recognized by their .aspx extension.

aspect-oriented programming

Aspect-oriented programming (AOP) is an approach to programming that allows global properties of a program to determine how it is compiled into an executable program. AOP can be used with object-oriented programming (OOP).

An *aspect* is a subprogram that is associated with a specific property of a program. As that property varies, the effect “ripples” through the entire program. The aspect subprogram is used as part of a new kind of **compiler** called an *aspect weaver*.

The conceptualizers of AOP compare aspect programming to the manufacturing of cloth in which threads are automatically interwoven. Without AOP, programmers must stitch the threads by hand.

ASPI

ASPI (Advanced SCSI Programming Interface) specifies how an application program can communicate with a **SCSI** (Small Computer System Interface) device through a common SCSI **device driver**. ASPI provides a set of functions that are common to any SCSI device.

Developed by Adaptec, ASPI has become the industry standard for controlling SCSI devices. The ASPI device driver is the program that actually interacts with the SCSI device. The layering looks something like this: application/utility, ASPI, ASPI driver, SCSI card.

ASPI driver

In a personal computer, an ASPI driver is a software **driver** or program that uses the Advanced SCSI Programming Interface (ASPI) **protocol** to interface with the Small Computer System Interface (**SCSI**) **bus**. The ASPI interface specification was developed by Adaptec as a means of sending commands to a SCSI **host** adapter. ASPI provides an **abstraction** layer that hides irrelevant details about the host adapter from the programmer and standardizes the interface to simplify application development.

Common Access Method (CAM), the main alternative to ASPI, performs the same basic tasks, but in a different and slightly more complicated way. CAM is not as widely used. ASPI is compatible with most operating systems, and has become the standard for enabling the development of **applications** and drivers that will work with all compatible SCSI adapters.

ASPIC

ASPIC (Application Service Provider Industry Consortium) is a non-profit, international advocacy group comprised of some 700 companies in nearly 30 countries. The ASPIC was formed in May, 1999 to promote and help create an understanding of the application service provider (ASP) industry by sponsoring research, establishing guidelines to promote best practices, and conveying the benefits of the ASP computing model.

assembler

An assembler is a **program** that takes basic computer **instructions** and converts them into a pattern of **bits** that the computer’s **processor** can use to perform its basic operations. Some people call these instructions assembler language and others use the term assembly language.

Here’s how it works:

- Most computers come with a specified set of very basic instructions that correspond to the basic machine operations that the computer can perform. For example, a “Load” instruction causes the processor to move a string of bits from a location in the processor’s **memory** to a special holding place called a **register**. Assuming the processor has at least eight registers, each numbered, the following instruction would move the value (string of bits of a certain length) at memory location 3000 into the holding place called register 8:
L 8,3000
- The programmer can write a program using a sequence of these assembler instructions.
- This sequence of assembler instructions, known as the **source code** or source program, is then specified to the assembler program when that program is started.
- The assembler program takes each program statement in the source program and generates a corresponding bit stream or pattern (a series of 0’s and 1’s of a given length).
- The output of the assembler program is called the **source code** or object program relative to the input source program. The sequence of 0’s and 1’s that constitute the object program is sometimes called **machine code**.
- The object program can then be run (or **executed**) whenever desired.

In the earliest computers, programmers actually wrote programs in machine code, but assembler languages or instruction sets were soon developed to speed up programming. Today, assembler programming is used only where very efficient control over processor operations is needed. It requires knowledge of a particular computer’s instruction set, however. Historically, most programs have been written in “higher-level” languages such as COBOL, FORTRAN, PL/I, and C. These languages are easier to learn and faster to write programs with than assembler language.

The program that processes the source code written in these languages is called a **compiler**. Like the assembler, a compiler takes higher-level language statements and reduces them to machine code.

A newer idea in program preparation and portability is the concept of a **virtual machine**. For example, using the **Java** programming language, language statements are compiled into a generic form of machine language known as **bytecode** that can be run by a virtual machine, a kind of theoretical machine that approximates most computer operations. The bytecode can then be sent to any computer platform that has previously downloaded or built in the Java virtual machine. The virtual machine is aware of the specific instruction lengths and other particularities of the platform and ensures that the Java bytecode can run.

Association for Computing Machinery

The Association for Computing Machinery (ACM), founded in 1947, is the largest and oldest international scientific and industrial computer society. Through its many Special Interest Groups, the ACM fosters research and communication in a broad range of computing areas.

Many of the Special Interest Groups publish their own journals or proceedings. There is a Usenet group at comp.org.acm.

ASSP

In computers, an ASSP (application-specific standard product) is a **semiconductor** device integrated circuit (IC) product that is dedicated to a specific **application** market and sold to more than one user (and thus, "standard"). The ASSP is marketed to multiple customers just as a general-purpose product is, but to a smaller number of customers since it is for a specific application. Like an ASIC (application-specific integrated circuit), the ASSP is for a special application, but it is sold to any number of companies. (An ASIC is designed and built to order for a specific company.)

An ASSP generally offers the same performance characteristics and has the same die size as an ASIC. According to a Dataquest study, 17% of all semiconductor products sold in 1999 were ASSPs; 83% were general-purpose. According to Dataquest's Jim Walker, the trend is toward more application-specific products.

asymmetric communications

For an example of asymmetric communications, see Asymmetric Digital Subscriber Line (ADSL).

In telecommunications, the term **asymmetric** (also **asymmetrical** or **non-symmetrical**) refers to any system in which the data speed or quantity differs in one direction as compared with the other direction, averaged over time. Asymmetrical data flow can, in some instances, make more

efficient use of the available infrastructure than symmetrical data flow, in which the speed or quantity of data is the same in both directions, averaged over time.

Consider an Internet connection in which downstream data (from an Internet server to the subscriber) flows over a **broadband satellite downlink**, while upstream data (from the end user to the server) is sent over a **twisted-pair** telephone line. This is an example of asymmetric communications. The hardware for reception of satellite signals is simple, consisting of a small dish **antenna**, an amplifier/converter, and a modem. While the downstream data might flow at 1 **MBps** or more, upstream data is limited to 56 kbps (often much less). In most Web browsing applications, this is a major improvement over a connection in which the upstream and downstream data both must flow through the twisted pair. This is because most of the bytes come downstream as relatively large graphics, sound, multimedia, and HTML files, while upstream data consists mainly of new content requests by the subscriber, which, in comparison, contain few bytes. In this environment, it would not make sense to supply the subscriber with the sophisticated hardware necessary for a broadband satellite uplink.

In some situations, asymmetric communications is not satisfactory. An example is two-way, full-motion video-conferencing, in which broadband data must flow in two directions between two end users. Another example is File Transfer Protocol (FTP) applications in which the volume of upstream data is considerable. For communications of this type, broadband cable modem, optical fiber, or broadband wireless Internet access is available in some locations. At the time of this writing, symmetric broadband is not generally available outside of metropolitan areas.

Asymmetric Digital Subscriber Line

See "ADSL"

asynchronous transfer mode

See "ATM"

asynchronous

In general, **asynchronous** (pronounced ay-SIHN-kro-nuhs, from Greek *asyn-*, meaning "not with," and *chronos*, meaning "time") is an adjective describing objects or events that are not coordinated in time. In information technology, the term has several different usages.

1) In telecommunication signaling within a network or between networks, an **asynchronous** signal is one that is transmitted at a different clock rate than another signal. (**Plesiochronous** signals are almost but not quite in synchronization—and a method is used to adjust them—and **synchronous** signals are those that run at the same clock rate.

2) In computer programs, asynchronous operation means that a process operates independently of other processes, whereas synchronous operation means that the process runs only as a result of some other process being completed or handing off operation. A typical activity that might use a synchronous protocol would be a transmission of files from one point to another. As each transmission is received, a response is returned indicating success or the need to resend. Each successive transmission of data requires a response to the previous transmission before a new one can be initiated.

Synchronous program communication is contrasted with **asynchronous** program communication.

AT Attachment Packet Interface

See “ATAPI”

at sign

On the Internet, @ (pronounced “at” or “at sign” or “address sign”) is the symbol in an **e-mail** address that separates the name of the user from the user’s Internet address, as in this hypothetical e-mail address example: msmuffet@tuffet.org.

In business, @ is a symbol meaning “at” or “each.” For example, it means “each” in “4 apples @ \$.35 = \$1.40.” Perhaps because it was one of the standard characters designed into typewriters (usually with the upper shift key pressed), the @ was chosen for inclusion as one of the special characters in the **ASCII** set of characters that became standard for computer keyboards, programs, and online message transmission. In July 1972, as the specifications for the File Transfer Protocol (**FTP**) were being written, someone suggested including some e-mail programs written by Ray Tomlinson, an engineer at Bolt Beranek and Newman, chief contractor on **ARPANet** (Advanced Research Projects Agency Network), the precursor of the Internet. In their book, *Where Wizards Stay Up Late*, Katie Hafner and Matthew Lyon describe how the @ sign got there:

Tomlinson...became better known for a brilliant (he called it obvious) decision he made while writing [the e-mail] programs. He needed a way to separate, in the e-mail address, the name of the user from the machine the user was on. How should that be denoted? He wanted a character that would not, under any circumstances, be found in the user’s name. He looked down at the keyboard he was using, a Model 33 Teletype, which almost everyone else on the Net used, too. In addition to the letters and numerals there were about a dozen punctuation marks. “I got there first, so I got to choose any punctuation I wanted,” Tomlinson said. “I chose the @ sign.” The character also had the advantage of meaning “at” the designated institution. He had no idea he was creating an icon for the wired world.

ATA

ATA (Advanced Technology Attachment) is the official name that **American National Standards Institute** group X3T10 uses for what the computer industry calls **Integrated Drive Electronics** (IDE).

ATAPI

ATAPI (AT Attachment Packet Interface) is an interface between your computer and attached **CD-ROM** drives and tape backup drives. Most of today’s PC computers use the standard **Integrated Drive Electronics** (IDE) interface to address hard disk drives. ATAPI provides the additional commands needed for controlling a CD-ROM player or tape backup so that your computer can use the IDE interface and controllers to control these relatively newer device types.

ATAPI is part of the Enhanced IDE (**EIDE**) interface (also known as *ATA-2*).

Athlon

Athlon, a popular **microprocessor** from AMD that is used in many personal computers, was the first processor to be shipped in a 1 **gigahertz** (one billion **clock speed**) version. Compaq and Gateway are among companies that will manufacture computers that include the 1 GHz Athlon. Athlon also comes in versions that have clock speeds somewhat below 1 GHz.

The second largest maker of microprocessors after Intel, AMD has gained on its rival in recent years. The Athlon achieved favorable press reviews for its speed and cost when compared to Intel’s **Pentium 3**. Athlon has an **x86-compatible** processor architecture that comes with a fully **pipelining**, superscalar **floating point unit**, a 128 **kilobyte L1 and L2** that is built into the microprocessor chip, and a programmable **backside bus** to a **L1 and L2**. A notable feature is the system’s 200 **MHz bus**. The Athlon chip uses AMD’s aluminum 0.18-**micron** technology.

As the successor to AMD’s K6 microprocessor, Athlon was previously called the K7.

ATL

See “Active Template Library”

ATM

ATM (asynchronous transfer mode) is a dedicated-connection switching technology that organizes digital data into 53-**byte cell** units and transmits them over a physical medium using digital signal technology. Individually, a cell is processed **asynchronously** relative to other related cells and is queued before being **multiplexed** over the transmission path.

Because ATM is designed to be easily implemented by hardware (rather than software), faster processing and **switch** speeds are possible. The prespecified bit rates are either 155.520 **Mbps** or 622.080 Mbps. Speeds on ATM networks can reach 10 **Gbps**. Along with Synchronous Optical Network (**SONET**) and several other technologies, ATM is a key component of broadband ISDN (**BISDN**).

ATM also stands for *automated teller machine*, a machine that bank customers use to make transactions without a human teller.

atom

An atom is a particle of matter that uniquely defines a chemical element. An atom consists of a central nucleus that is usually surrounded by one or more electrons. Each **electron** is negatively charged. The nucleus is positively charged, and contains one or more relatively heavy particles known as *protons* and *neutrons*.

A proton is positively charged. The number of protons in the nucleus of an atom is the *atomic number* for the chemical element. A proton has a rest mass, denoted m_p , of approximately 1.673×10^{-27} kilogram (kg). A neutron is electrically neutral and has a rest mass, denoted m_n , of approximately 1.675×10^{-27} kg. The mass of a proton or neutron increases when the particle attains extreme speed, for example in a cyclotron or linear accelerator.

An early model of the atom was developed by the physicist Ernest Rutherford in 1912. He was the first to suggest that atoms are like miniature solar systems, except that the attractive force is not caused by gravity, but by opposing electrical charges. In the so-called *Rutherford atom*, electrons orbit the nucleus in circular paths. Niels Bohr revised Rutherford's theory in 1913. In the *Bohr atom*, the negatively charged electrons orbit the nucleus at specific median distances. These distances are represented by spheres, called *shells*, surrounding the nucleus. Electrons can move from shell to shell. When an electron absorbs enough energy, it moves to a larger, or higher, shell. When it loses a certain amount of energy, it falls to a smaller, or lower, shell.

The total mass of an atom, including the protons, neutrons and electrons, is the *atomic mass* or *atomic weight*. Electrons contribute only a tiny part of this mass. For most practical purposes, the atomic weight can be thought of as the number of protons plus the number of neutrons. Because the number of neutrons in an atom can vary, there can be several different atomic weights for most elements.

Atoms having the same number of protons, but different numbers of neutrons, represent the same element, but are known as different *isotopes* of that element. The isotope for an element is specified by the sum of the number of protons and neutrons. Examples of different isotopes of an element are carbon 12 (the most common, non-radioactive isotope of carbon) and carbon 14 (a less common, radioactive isotope of carbon).

Protons and electrons have equal and opposite charge, and normally an atom has equal numbers of both. Thus, atoms are usually neutral. An *ion* is an atom with extra electrons or with a deficiency of electrons, resulting in its being electrically charged. An ion with extra electrons is negatively charged and is called an *anion*; an ion deficient in electrons is positively charged and is called a *cation*.

atomic

In ancient philosophy, an atom was the ultimate unit of matter on which more complex views of material reality were based. In computer programming, atomic describes a unitary action or object that is essentially indivisible, unchangeable, whole, and irreducible. Here are some usages:

- 1) In **Structured Query Language**, an atomic function is one that will either complete or return to its original state if a power interruption or an abnormal end occurs.
- 2) In some **UNIX**-base operating systems, an atomic operation is one in which no change can take place in the time between the setting of a mask and the receiving of a signal to change the mask.
- 3) In some programming languages, including Lisp, an *atom* is the basic unit of executable code or data.

atomic force microscopy

Atomic force microscopy (AFM) is a technique for analyzing the surface of a rigid material all the way down to the level of the **atom**. AFM uses a mechanical probe to magnify surface features up to 100,000,000 times, and it produces 3-D images of the surface.

The technique is derived from a related technology, called scanning tunneling microscopy (STM). The difference is that AFM does not require the sample to conduct electricity, whereas STM does. AFM also works in regular room temperatures, while STM requires special temperature and other conditions.

AFM is being used to understand materials problems in many areas, including data storage, telecommunications, biomedicine, chemistry, and aerospace. In data storage, it is helping researchers to "force" a disk to have a higher capacity. Today's magnetic storage devices typically have a capacity limit of between 20 and 50 gigabits (billions of bits) per square inch of storage medium. Researchers are looking into AFM to help raise read and write densities to between 40 gigabits and 300 gigabits per square inch. No one has yet commercialized AFM technology for this purpose, but IBM and others are actively pursuing it.

atomicity, consistency, isolation, and durability

See "ACID"

ATSC

See “Advanced Television Systems Committee”

attachment unit interface

See “AUI”

attempt

In a telecommunications system, an attempt is a user request to get connected to the system or to initiate a call, whether or not the connection is made or the call is initiated.

attenuation

Attenuation is a general term that refers to any reduction in the strength of a **signal**. Attenuation occurs with any type of signal, whether **digital** or **analog**. Sometimes called *loss*, attenuation is a natural consequence of signal transmission over long distances. The extent of attenuation is usually expressed in units called *decibels*.

If P_s is the signal power at the transmitting end (source) of a communications circuit and P_d is the signal power at the receiving end (destination), then $P_s > P_d$. The power attenuation A_p in decibels is given by the formula:

$$A_p = 10 \log_{10}(P_s/P_d)$$

Attenuation can also be expressed in terms of voltage. If A_v is the voltage attenuation in decibels, V_s is the source signal voltage, and V_d is the destination signal voltage, then:

$$A_v = 20 \log_{10}(V_s/V_d)$$

In conventional and fiberoptic cables, attenuation is specified in terms of the number of decibels per foot, 1,000 feet, kilometer, or mile. The less the attenuation per unit distance, the more efficient the cable. When it is necessary to transmit signals over long distances via cable, one or more **repeaters** can be inserted along the length of the cable. The repeaters boost the signal strength to overcome attenuation. This greatly increases the maximum attainable range of communication.

attosecond

(This definition follows U.S. usage in which a billion is a thousand million and a trillion is a 1 followed by 12 zeros.)

An attosecond is one quintillionth (10^{-18}) of a **second** and is a term used in **photon** research.

For comparison, a millisecond (ms or msec) is one thousandth of a second and is commonly used in measuring the time to read to or write from a **hard disk** or a **CD-ROM** player or to measure **packet** travel time on the Internet.

A microsecond (μ s or Greek letter mu plus s) is one millionth (10^{-6}) of a second.

A nanosecond (ns or nsec) is one billionth (10^{-9}) of a second and is a common measurement of read or write access time to random access memory (**RAM**).

A picosecond is one trillionth (10^{-12}) of a second, or one millionth of a microsecond.

A femtosecond is one millionth of a nanosecond or 10^{-15} of a second and is a measurement sometimes used in **laser** technology.

attribute

In general, an attribute is a property or characteristic. Color, for example, is an attribute of your hair. In using or programming computers, an attribute is a changeable property or characteristic of some component of a program that can be set to different values.

In the Hypertext Markup Language (**HTML**), an attribute is a characteristic of a page element, such as a font. An HTML user can set font attributes, such as size and color, to different values. In some programming languages, such as **PowerBuilder** PowerScript, an attribute is a property of an **object** or may be considered a container for the property of the object. For example, color might be an attribute of a text object, containing the value of “red.”

In a database management system (**DBMS**), an attribute may describe a component of the database, such as a table or a **field**, or may be used itself as another term for a field.

In the **DOS** operating system, file properties, such as “read-only” or “visible,” are called file attributes.

ATU-R

An ATU-R (ADSL Terminal Unit—Remote), sometimes called an “ADSL modem,” is a hardware unit that is installed in any computer that uses a telephone company connection with Asymmetric Digital Subscriber Line (**ADSL**) service. The ATU-R connects to an **Ethernet** network interface card (**NIC**) in the computer and, on the other side, to a telephone jack in the home or business. Ideally (for less interference), the telephone jack hooks up to a new wire that goes to a signal **splitter** that the telephone company installs at the telephone company demarcation point (the place where the outside phone company wire or wires connect to the network of phone lines within the customer’s building). The splitter divides the signal into low frequencies for voice and high frequencies for data.

ATV

ATV (Advanced Television) is the name given by the U.S. Federal Communications Commission to digital TV (**DTV**), the use of digital transmission of video and audio information on broadcast channels and **cable TV**. ATV includes both high-definition television (**HDTV**), a format

for digital video compression, transmission, and presentation and also the creation of additional channels on the current **analog 6 MHz** channel.

For additional information, see **HDTV**.

ATX

ATX is an industry-wide **open** specification for a desktop computer's **motherboard**. The most current version (December, 1996) is Specification 2.0.

ATX improves the motherboard design by taking the small AT motherboard that has been an industry standard and rotating by 90 degrees the layout of the **microprocessor** and expansion **slots**. This allows space for more full-length add-in **cards**. A double-height aperture is specified for the rear of the chassis, allowing more possible I/O arrangements for a variety of devices such as TV input and output, LAN connection, and so forth. The new layout is also intended to be less costly to manufacture. Fewer cables will be needed. The power supply has a side-mounted fan, allowing direct cooling of the processor and cards, making a secondary fan unnecessary. Version 2.0 incorporates improvements suggested by chassis and power supply vendors.

Almost all major computer manufacturers, including IBM, Compaq, and Apple build desktops with ATX motherboards. IBM is using ATX in both Intel and PowerPC platforms.

audible ring

In a telephone system, an audible ring is the tone that is returned from the called party's switching device and heard by the caller. This tone indicates to the caller that the desired party is being rung.

audio

Audio is sound within the acoustic range available to humans. An audio frequency (**AF**) is an electrical alternating current within the 20 to 20,000 **hertz** (cycles per second) range that can be used to produce acoustic sound. In computers, audio is the sound system that comes with or can be added to a computer. An audio **card** contains a special built-in processor and memory for processing audio files and sending them to *speakers* in the computer. An audio file is a record of captured sound that can be played back. Sound is a sequence of natural **analog** signals that are converted to **digital** signals by the audio card, using a microchip called an analog-to-digital converter (**ADC**). When sound is played, the digital signals are sent to the speakers where they are converted back to analog signals that generate varied sound.

Audio files are usually **compressed** for storage or faster transmission. Audio files can be sent in short stand-alone segments—for example, as files in the **Wave file** format. In order for users to receive sound in real-time for a multimedia effect, listening to music, or in order to take part

in an audio or video conference, sound must be delivered as **streaming sound**. More advanced audio cards support **wavetable**, or precaptured tables of sound. The most popular audio file format today is **MP3** (MPEG-1 Audio Layer-3).

Audio Engineers Society/European Broadcasting Union

AES/EBU (Audio Engineering Society/European Broadcasting Union) is the name of a **digital audio** transfer standard. The AES and EBU developed the specifications for the standard.

The AES/EBU digital interface is usually implemented using **3-pin XLR** connectors, the same type connector used in a professional microphone. One cable carries both left- and right-channel audio data to the receiving device. AES/EBU is an alternative to the **S/PDIF** standard.

audio frequency

See "AF"

audio noise

Also see **noise**.

In **audio**, noise is generally any unpleasant sound and, more technically, any unwanted sound that is unintentionally added to a desired sound. Ambient sound itself is a series of changes in air pressure transmitted in waves from the sound source to anyone with the sensory apparatus to detect the waves (human beings and other animals with ears, for example). Sound waves are expressed as a series of **analog** sine waves. The combination and blend of these waves gives sounds their individual characteristics, making them pleasant or unpleasant to listen to. Some sounds are combination of waves that are related to each other, as in the case of a pitched instrument that transmits one dominant frequency of sound wave and additional frequencies that enhance the fundamental or dominant frequency. An oboe is an example of a pitched instrument. Other sounds are made from a grouping of tightly spaced waves that do not have a specific fundamental frequency that is dominant over the others. A snare drum is an example.

In recording sound, noise is often present on analog tape or low-fidelity digital recordings. The standard audio cassette includes a layer of hiss on every recording. When doing digital recording, the conversion of a sound file from 16-bit to 8-bit adds a layer of noise.

White noise is a sound that contains every frequency within the range of human hearing (generally from 20 **hertz** to 20 **kHz**) in equal amounts. Most people perceive this sound as having more high-frequency content than low, but this is not the case. This perception occurs because each successive octave has twice as many frequencies as the one preceding it.

For example, from 100 Hz to 200 Hz, there are one hundred discrete frequencies. In the next octave (from 200 Hz to 400 Hz), there are two hundred frequencies.

White noise can be generated on a sound synthesizer. Sound designers can use this sound, with some processing and filtering, to create a multitude of effects such as wind, surf, space whooshes, and rumbles.

Pink noise is a variant of white noise. Pink noise is white noise that has been filtered to reduce the volume at each octave. This is done to compensate for the increase in the number of frequencies per octave. Each octave is reduced by 6 **decibels**, resulting in a noise sound wave that has equal energy at every octave.

Audio/Modem Riser

See “AMR”

audio/video

See “AV”

audit trail

In accounting, an audit trail is the sequence of paperwork that validates or invalidates accounting entries. In computing, the term is also used for an electronic or paper log used to track computer activity. For example, a corporate employee might have access to a section of a network in a corporation such as billing but be unauthorized to access all other sections. If that employee attempts to access an unauthorized section by typing in passwords, this improper activity is recorded in the audit trail.

Audit trails are used to record customer activity in e-commerce. The customer’s initial contact is recorded in an audit trail as well as each subsequent action such as payment and delivery of the product or service. The customer’s audit trail is then used to respond properly to any inquiries or complaints. A company might also use an audit trail to provide a basis for account reconciliation, to provide a historical report to plan and support budgets, and to provide a record of sales in case of a tax audit.

Audit trails are also used to investigate cybercrimes. In order for investigators to expose a hacker’s identity, they can follow the trail the hacker left in cyberspace. Sometimes hackers unknowingly provide audit trails through their Internet service providers’ activity logs or through chat room logs.

auditor

In Web advertising, this usually means a third-party company that audits the number of visitors to or **impression** sent from a Web site during some time period. When you try to sell advertising, having a third-party auditor gives the prospect more confidence in your audience numbers.

AUI

The AUI (attachment unit interface) is the 15-pin physical connector interface between a computer’s network interface card (NIC) and an **Ethernet** cable. On **10Base-5** (“thicknet”) Ethernet, a short cable is used to connect the AUI on the computer with a transceiver on the main cable. In **10Base-2** or “thinnet” Ethernet networks, the NIC connects directly to the Ethernet coaxial cable at the back of the computer.

IEEE 802.3, the Ethernet standard, defines the AUI 15-pin physical layer interface. This interface is also called a DB-15 interface or a DIX interface (DIX refers to the three major companies who helped standardize Ethernet: Digital Equipment Corporation, Intel, and Xerox).

AUP

See “acceptable use policy”

authentication

Authentication is the process of determining whether someone or something is, in fact, who or what it is declared to be. In private and public computer networks (including the Internet), authentication is commonly done through the use of **logon** passwords. Knowledge of the password is assumed to guarantee that the user is authentic. Each user registers initially (or is registered by someone else), using an assigned or self-declared password. On each subsequent use, the user must know and use the previously declared password. The weakness in this system for transactions that are significant (such as the exchange of money) is that passwords can often be stolen, accidentally revealed, or forgotten.

For this reason, Internet business and many other transactions require a more stringent authentication process. The use of **digital certificates** issued and verified by a Certificate Authority (CA) as part of a **public key infrastructure** is considered likely to become the standard way to perform authentication on the Internet.

Logically, authentication precedes **authorization** (although they may often seem to be combined).

authentication, authorization, and accounting

Authentication, authorization, and accounting (AAA) is a term for a framework for intelligently controlling access to computer resources, enforcing policies, auditing usage, and providing the information necessary to bill for services. These combined processes are considered important for effective network management and security.

Authentication provides a way of identifying a user, typically by having the user enter a valid user name and valid password before access is granted. The process of authentication is based on each user having a unique set of criteria for gaining access. The AAA server compares a user's authentication credentials with other user credentials stored in a database. If the credentials match, the user is granted access to the network. If the credentials are at variance, authentication fails and network access is denied.

Following authentication, a user must gain **authorization** for doing certain tasks. After logging into a system, for instance, the user may try to issue commands. The authorization process determines whether the user has the authority to issue such commands. Simply put, authorization is the process of enforcing policies: determining what types or qualities of activities, resources, or services a user is permitted. Usually, authorization occurs within the context of authentication. Once you have authenticated a user, they may be authorized for different types of access or activity.

The final plank in the AAA framework is accounting, which measures the resources a user consumes during access. This can include the amount of system time or the amount of data a user has sent and/or received during a session. Accounting is carried out by logging of session statistics and usage information and is used for authorization control, billing, trend analysis, resource utilization, and capacity planning activities.

Authentication, authorization, and accounting services are often provided by a dedicated **AAA server**, a program that performs these functions. A current standard by which network access servers interface with the AAA server is the Remote Authentication Dial-In User Service (**RADIUS**).

authorization

Authorization is the process of giving someone permission to do or have something. In multi-user computer systems, a system administrator defines for the system which users are allowed access to the system and what privileges of use (such as access to which file directories, hours of access, amount of allocated storage space, and so forth). Assuming that someone has logged in to a computer **operating system** or **application**, the system or application may want to identify what resources the user can be given during this session. Thus, authorization is sometimes seen as both the

preliminary setting up of permissions by a system administrator and the actual checking of the permission values that have been set up when a user is getting access.

Logically, authorization is preceded by **authentication**.

authorized program analysis report

An APAR (authorized program analysis report) is a term used in IBM for a description of a problem with an IBM program that is formally tracked until a solution is provided. An APAR is created or "opened" after a customer (or sometimes IBM itself) discovers a problem that IBM determines is due to a bug in its code. The APAR is given a unique number for tracking and a target date for solution. When the support group that maintains the code solves the problem, it develops a *program temporary fix (PTF)* that, when applied, possibly with a **SuperZap**, will temporarily solve the problem for the customers that may be affected. The PTF will "close" the APAR. PTFs can be applied individually but are usually made available as part of a *fix package* that includes a number of PTFs. Meanwhile, the PTFs are provided to the development group that is working on the next product release. The developers may or may not use the PTFs (since these are temporary fixes), but will determine and design the correct problem solution to incorporate in the next product release.

autoexec.bat

AUTOEXEC.BAT is a file containing **Disk Operating System commands** that are **executable** when the computer is **booted** (started). The commands in AUTOEXEC.BAT tell the **operating system** which application programs are to be automatically started, how memory is to be managed, and initialize other settings. Each command in AUTOEXEC.BAT could be typed in manually after the computer is started, but that would take too long. The AUTOEXEC.BAT file is, in fact, a command **script** that is written beforehand so that it can be automatically executed when the operating system is started. The BAT suffix stands for **batch**, indicating that this is a file containing a sequence of commands entered from a file rather than interactively by a user.

automagically

Automagically is a term used when the user either doesn't want to go into the technical details of something or doesn't know the details but does know what the end result has to be. The term is sometimes used in planning and design discussions and trade show demonstrations. For example, one might say:

"Our new CD-ROM will put a handy button on your computer desktop automagically. You won't even have to think about it."

The term is a playful variation of *automatically*.

Automated Clearing House

Automated Clearing House (ACH) is a secure payment transfer system that connects all U.S. financial institutions. The ACH network acts as the central clearing facility for all Electronic Fund Transfer (EFT) transactions that occur nationwide, representing a crucial link in the national banking system. It is here that payments linger in something akin to a holding pattern while awaiting clearance for their final banking destination. Scores of financial institutions transmit or receive ACH entries through ACH operators such as the American Clearing House Association, the Federal Reserve, the Electronic Payments Network, and Visa.

In 1998, the network processed nearly 5.3 billion ACH transactions with a total value of more than \$16 trillion.

Automatic Call Distributor

An Automatic Call Distributor (ACD) is a telephone facility that manages incoming calls and handles them based on the number called and an associated **database** of handling instructions. Many companies offering sales and service support use ACDs to validate callers, make outgoing responses or calls, forward calls to the right party, allow callers to record messages, gather usage statistics, balance the use of phone lines, and provide other services.

ACDs often provide some form of Automatic Customer/ Caller Identification (ACIS) such as that provided by Direct Inward Dialing (DID), Dialed Number Identification Service (DNIS), or Automatic Number Identification (ANI).

Automatic Coin Telephone System

Automatic Coin Telephone System (ACTS) is a public coin-operated telephone service that completes a variety of phone calls, times the calls, and collects payment without the aid of an operator.

automatic language translation

Automatic language translation is the use of a computer program to translate input text from one national language to another while maintaining the original document format. Yahoo and some other sites offer what is sometimes called **instant translation** using such a tool. Since language is heavily dependent on context and connoted as well as denoted meaning, a program needs to have access to such context as well as the ability to use it. Since providing enough context is difficult, automatic language translation thus far seems to be successful only in limited and well-understood situations and as a first time-saving step toward translation (or "post-editing") by a human being.

Automatic Number Identification

See "ANI"

automatic vehicle locator

An automatic vehicle locator (AVL) is a device that makes use of the Global Positioning System (GPS) to enable a business or agency to remotely track the location of its vehicle fleet by using the Internet. These devices combine GPS technology, cellular communications, street-level mapping, and an intuitive user interface, with the ostensible goal of improving fleet management and customer service. For example, a company using an AVL system is able to pinpoint the longitude, latitude, ground speed, and course direction of a given vehicle. The vehicle's location can be quickly found and it could be rerouted to provide timely delivery to a nearby customer. AVL systems also enable companies to structure delivery routes more efficiently by compiling a database of vehicle information, including location of customers in relation to established delivery routes.

AVL systems generally include a network of vehicles that are equipped with a mobile radio receiver, a GPS receiver, a GPS modem, and a GPS antenna. This network connects with a base radio consisting of a PC computer station as well as a GPS receiver and interface. GPS uses interactive maps rather than static map images on the Web. This means users can perform conventional GPS functions such as zoom, pan, identify and queries.

AVL systems can be used to increase the accountability of field personnel and boost the efficiency of a company's dispatching procedure. Dispatchers can get a real-time snapshot of driver adherence to a route, provide customers with an estimated time of arrival, and communicate directly with drivers. Public safety agencies, such as police departments or fire departments, can use AVL technology to improve response times by being able to dispatch the closest vehicles for emergencies.

Most AVL suppliers have created products that don't require dedicated servers and require minimal training of dispatchers. AVL systems use mouse clicks instead of keystrokes to page a single vehicle, a designated group of vehicles or an entire fleet. The Aertrax system, for example, operates without expensive receivers or other equipment. It can be operated with a PC or desktop that connects to the Internet. Aertrax includes a completely self-contained unit that uses a minimal amount of power from the vehicle in which it is installed. This unit transmits GPS location data, either on a regularly timed basis or in response to a command. This data is then converted into mapping that is instantly available via the Internet.

In Corpus Christi, Texas, a regional transit authority is collaborating with Texas AM University-Corpus Christi to develop an AVL system that not only would enable it to track bus locations but also enable automated ridership data collection and dynamic routing. Until recently, the availability of GPS to the commercial and civil sectors had been controlled by the U.S. Department of Defense through

an internationally imposed degradation standard known as Selective Availability. This standard degraded the accuracy of civilian GPS so that the highest degree of accuracy was reserved for the military. SA restrictions have since been lifted, enabling GPS to be dispersed for commercial application.

autonomous robot

See "robot"

autonomous system

On the Internet, an autonomous system (AS) is the unit of **router** policy, either a single network or a group of **network** that is controlled by a common network administrator (or group of administrators) on behalf of a single administrative entity (such as a university, a business enterprise, or a business division). An autonomous system is also sometimes referred to as a routing **domain**. An autonomous system is assigned a globally unique number, sometimes called an Autonomous System Number (ASN).

Networks within an autonomous system communicate routing information to each other using an **Interior Gateway Protocol** (IGP). An autonomous system shares routing information with other autonomous systems using the **Border Gateway Protocol** (BGP). Previously, the **Exterior Gateway Protocol** (EGP) was used. In the future, the BGP is expected to be replaced with the **OSI Inter-Domain Routing Protocol** (IDRP).

The Internet's protocol guideline for autonomous systems, after offering a definition similar to the one above, provides a more technical definition as follows:

An AS is a connected group of one or more **Internet Protocol** prefixes run by one or more network operators which has a SINGLE and CLEARLY DEFINED routing policy.

autoresponder

An autoresponder is a computer program that automatically returns a prewritten message to anyone who submits **e-mail** to a particular Internet address, whether an individual or a Web site. Autoresponders are widely used by Web sites for the purpose of responding to visitor comments and suggestions in a preliminary way and, in cases where traffic is heavy, as the sole way to communicate with user inquiries.

Publishers of **ezone** and other online e-mail newsletters typically use an autoresponder to respond to people who subscribe or cancel their subscriptions.

auxiliary storage

Auxiliary storage is all addressable data **storage** that is not currently in a computer's **main storage** or **memory**. Synonyms are **external storage** and **secondary storage**.

AV

AV, an abbreviation for audio/video, is frequently used as a generic term for the audio and video components and capabilities in home entertainment system and related product descriptions and reviews.

availability

1) In a telephone **circuit**, availability is the ratio between the time during which the circuit is operational and elapsed time.

2) In a network switching system, availability is the accessibility of input and output **ports**.

avatar

In **3D** or **virtual reality** games and in some **chat** forums on the Web, your avatar is the visual "handle" or display appearance you use to represent yourself. On Worlds Chat and similar sites, you can be a unicorn, a bluebird, or any kind of creature or object that seems right.

In the Hindu religion, an avatar is an incarnation of a deity; hence, an embodiment or manifestation of an idea or greater reality.

average bouncing busy hour

In designing and assessing **networks**, one approach is to measure the average bouncing busy hour (ABBH) traffic in various network **trunks** or trunk groups of the network. The ABBH is the traffic load on a switching system during the peak (most busy) hour of each day, over a certain period, typically one week, then averaged for the time period.

Another traditional index to peak traffic is the **10-high-day busy period**.

AVI file

An AVI (Audio Video Interleaved) file is a sound and motion picture file that conforms to the Microsoft Windows Resource Interchange File Format (RIFF) specification. AVI files (which end with an .avi extension) require a special player that may be included with your Web browser or may require downloading.

Avogadro Constant

See "mole per meter cubed"

AWG

See "American Wire Gauge"

awk

awk (also written as Awk and AWK) is a utility that enables a programmer to write tiny but effective programs in the form of statements that define text patterns that are to be searched for in each line of a document and the action that is to be taken when a match is found within a line. awk comes with most **UNIX**-based operating systems such as **Linux**, and also with some other operating systems, such as Windows 95/98/NT.

An awk program is made up of patterns and actions to be performed when a pattern match is found. awk scans input lines sequentially and examines each one to determine whether it contains a pattern matching one specified by the user. When the matching pattern is found, awk carries out the instructions in the program. For example, awk could scan text for a critical portion and reformat the text contained in it according to the user's command. If no pattern is specified, the program will carry out the command on all of the input data.

awk breaks each line into fields, which are groups of characters with spaces acting as separators so that a word, for example, would be a field. A string is encased in backslashes and actions to be performed are encased in curly brackets. The lines are numbered in order of their appearance, with "0" referring to the entire line. "\$" is the symbol for field. So, for example, to search for a line containing the word "nutmeg," and to print each line in which the word occurs, the awk program would consist of:

```
/nutmeg/ { print $0 }.
```

The name "awk" is derived from the names of its three developers: Alfred Aho, Peter Weinberger, and Brian Kernighan. It was developed from **grep**, **C**, and **sed** syntax, a combination that allows complex programs to be developed quickly. awk is frequently used for prototyping. Versions of awk include **Portable Operating System Interface** awk, **New awk** (Nawk) and **GNU awk** (Gawk). The **Practical Extraction and Reporting Language** language was developed as an improved version of awk, with which Perl is **backward compatible**.

B channel

See “B-channel”

B2B

On the Internet, B2B (business-to-business), also known as e-biz, is the exchange of products, services, or information between businesses rather than between businesses and consumers. Although early interest centered on the growth of retailing on the Internet (sometimes called **e-tailing**), forecasts are that B2B revenue will far exceed business-to-consumers (B2C) revenue in the near future. According to studies published in early 2000, the money volume of B2B exceeds that of e-tailing by 10 to 1. Over the next five years, B2B is expected to have a compound annual growth of 41%. The Gartner Group estimates B2B revenue worldwide to be \$7.29 trillion dollars by 2004. In early 2000, the volume of investment in B2B by venture capitalists was reported to be accelerating sharply although profitable B2B sites were not yet easy to find.

B2B Web sites can be sorted into:

- **Company Web sites**, since the target audience for many company Web sites is other companies and their employees. Company sites can be thought of as round-the-clock mini-trade exhibits. Sometimes a company Web site serves as the entrance to an exclusive **extranet** available only to customers or registered site users. Some company Web sites sell directly from the site, effectively e-tailing to other businesses.
- **Product supply and procurement exchanges**, where a company purchasing agent can shop for supplies from vendors, request proposals, and, in some cases, bid to make a purchase at a desired price. Sometimes referred to as **e-procurement** sites, some serve a range of industries and others focus on a niche market.
- **Specialized or vertical industry portals** which provide a “subWeb” of information, product listings, discussion groups, and other features. These vertical **portal** sites have a broader purpose than the procurement sites (although they may also support buying and selling).
- **Brokering sites** that act as an intermediary between someone wanting a product or service and potential providers. Equipment leasing is an example.

- **Information sites** (sometimes known as **infomediary**), which provide information about a particular industry for its companies and their employees. These include specialized search sites and trade and industry standards organization sites. Many B2B sites may seem to fall into more than one of these groups. Models for B2B sites are still evolving.

Another type of B2B enterprise is software for building B2B Web sites, including site building tools and templates, **database**, and methodologies as well as transaction software.

B2B is **e-commerce** between businesses. An earlier and much more limited kind of online B2B prior to the Internet was Electronic Data Interchange (**EDI**), which is still widely used.

B2C

B2C is short for *business-to-consumer*, or the retailing part of e-commerce on the Internet. It is often contrasted to **B2B** or *business-to-business*.

B2E

B2E is business-to-employee, an approach in which the focus is the employee, rather than the consumer (as it is in business-to-consumer, or **B2C**) or other businesses (as it is in business-to-business, or **B2B**). The B2E approach grew out of the ongoing shortage of information technology (**IT**) workers. In a broad sense, B2E encompasses everything that businesses do to attract and retain well-qualified staff in a competitive market, such as aggressive recruiting tactics, benefits, education opportunities, flexible hours, bonuses, and employee empowerment strategies.

More specifically, the term “B2E” is frequently used to refer to the B2E portal (sometimes called a *people portal*), which is a customized **home page** or **desktop** for everyone within an organization. The B2E portal is sometimes considered to be synonymous with an **intranet**, but it differs in its focus on the employee’s desires. The intranet’s focus is the organization; the B2E portal focus is the individual. The B2E portal is designed to include not only everything that an employee might hope to find on an intranet (such as a corporate directory, or customer support information), but also any personal information and links that the employee might want (such as stocks information, or even games). The intention is to increase not only efficiency, but also employee satisfaction and a sense of community within the organization.

V,W

X,Y,Z

A B2E portal has three distinguishing characteristics:

- A single point of entry: one URL for everyone within an organization.
- A mixture of organization-specific and employee-defined components.
- The potential to be highly customized and easily altered to suit the particular employee.

Corporations may develop their own portals or they may rely on the services of any of the large and growing number of B2E portal developers.

B2G

On the Internet, B2G is business-to-government (a variation of the term **B2B** or business-to-business), the concept that businesses and government agencies can use central Web sites to exchange information and do business with each other more efficiently than they usually can off the Web. For example, a Web site offering B2G services could provide businesses with a single place to locate applications and tax forms for one or more levels of government (city, state or province, country, and so forth); provide the ability to send in filled-out forms and payments; update corporate information; request answers to specific questions; and so forth. B2G may also include **e-procurement** services, in which businesses learn about the purchasing needs of agencies and agencies request proposal responses. B2G may also support the idea of a **virtual workplace** in which a business and an agency could coordinate the work on a contracted project by sharing a common site to coordinate online meetings, review plans, and manage progress. B2G may also include the rental of online applications and databases designed especially for use by government agencies.

According to the Gartner Group, B2G revenue is expected to grow from \$1.5 billion in 2000 to \$6.2 billion in 2005. B2G is sometimes called *e-government*.

B8ZS

B8ZS (bipolar 8-zero substitution, also called *binary 8-zero substitution*, *clear channel*, and *clear 64*) is an encoding method used on T1 circuits that inserts two successive ones of the same **voltage**—referred to as a **bipolar violation**—into a signal whenever eight consecutive zeros are transmitted. The device receiving the signal interprets the bipolar violation as a timing mark, which keeps the transmitting and receiving devices synchronized. Ordinarily, when successive ones are transmitted, one has a positive voltage and the other has a negative voltage.

B8ZS is based on an older encoding method called alternate mark inversion (**AMI**). AMI is used with Dataphone Digital Service, the oldest data service still in use that uses 64 Kbps channels. AMI, however, requires the use of 8 Kbps of the 64 Kbps of each channel to maintain synchronization. In a T1

circuit, there are 24 channels. This loss adds up to 192 Kbps, which means that in reality only 56 Kbps is available for data transmission. B8ZS uses bipolar violations to synchronize devices, a solution that does not require the use of extra bits, which means a T1 circuit using B8ZS can use the full 64 Kbps for each channel for data. B8ZS is not compatible with older AMI equipment.

T1 technology is used in the United States and Japan. In Europe, a comparable technology called **E1** provides 32 channels instead of 24 and uses an encoding scheme called high-density bipolar 3 (HDB3) instead of B8ZS.

Babbage

See “Charles Babbage”

Back Orifice

Back Orifice is a **rootkit** program designed for the purpose of exposing the security deficiencies of Microsoft’s Windows **operating systems**. The program’s name is inspired by the name of Microsoft’s BackOffice product. Created by a group of **hackers** called the Cult of the Dead Cow, Back Orifice allows someone at one computer to control everything on another, remote computer running Windows 95 or later. Back Orifice can **sniff** passwords, record keystrokes, access a desktop’s file system and more, while remaining undetected.

Back Orifice is provided free as an **open source** program. It can then be delivered to unsuspecting users as a **Trojan horse** for hacking purposes, or used as a networked remote administration tool.

Back Orifice 2000 (BO2K) allows access to Windows NT and 2000, in addition to 95 and 98. BO2K has the same capabilities as Back Orifice, plus it uses cryptography for secure network administration and features extended plugin architecture for flexibility.

backbone

A backbone is a larger transmission line that carries data gathered from smaller lines that interconnect with it.

1) At the local level, a backbone is a line or set of lines that local area networks connect to for a wide area network connection or within a local area network to span distances efficiently (for example, between buildings).

2) On the Internet or other wide area network, a backbone is a set of paths that local or regional networks connect to for long-distance interconnection. The connection points are known as network *nodes* or telecommunication data switching exchanges (DSEs).

back-end

Front-end and back-end are terms used to characterize program interfaces and services relative to the initial user of these interfaces and services. (The “user” may be a human

being or a program.) A “front-end” **application** is one that application users interact with directly. A “back-end” application or program serves indirectly in support of the front-end services, usually by being closer to the required resource or having the capability to communicate with the required resource. The back-end application may interact directly with the front-end or, perhaps more typically, is a program called from an intermediate program that mediates front-end and back-end activities.

For example, the Telephone Application Program Interface (**TAPI**) is sometimes referred to as a front-end interface for telephone services. A program’s TAPI requests are mapped by Microsoft’s TAPI Dynamic Link Library programs (an intermediate set of programs) to a “back-end” program or **driver** that makes the more detailed series of requests to the telephone hardware in the computer.

As another example, a front-end application might interface directly with users and forward requests to a remotely-located back-end program in another computer to get requested data or perform a requested service. Relative to the **client/server** computing model, a front-end is likely to be a client and a back-end to be a server.

backhaul

Backhaul, a term probably derived from the trucking industry, has several usages in information technology.

1) In **satellite** communication, backhaul is used to mean getting data to a point from which it can be distributed over a network. For example, to deliver a live television program from Chicago to authorized DirecPC satellite terminals around the country, the video signals would have to be backhauled by some means (by **optical fiber** cable or by another satellite system) to the Hughes DirecPC facility in Germantown, Maryland. From there, it would be *uplinked* to the Galaxy IV satellite from which DirecPC users could view the broadcast (receive it in a downlink from the satellite at their individual terminals). Backhauling is also used to get non-live audio and video material to distribution points at the major broadcast news organizations for broadcast in the evening or ongoing news.

2) Manufacturers of network switching equipment use the term to mean “getting data to the network **backbone**” (which is similar to its use in the satellite communication industry). For example, Ascend uses the term to describe how its MAX 2000 switch can be used to interconnect data from a backhaul T-1 line on which mobile and remote office users are connected to an Internet service provider and the backbone of the Internet.

3) Backhauling is sending network data over an out-of-the-way route (including taking it farther than its destination) in order to get the data there sooner or because it costs less. This kind of backhauling involves understanding changing network conditions and economics.

4) Backhauling may sometimes be used to mean the use of the *back channel* on a bidirectional communications line.

backlink

In **Hyper-G** and possibly other **hypertext** systems, a backlink is a link back to the page or one of the pages that currently link to the page you’re using. Backlinks are already supported to some extent in the present Web system. Using JavaScript or a similar technique, you can add a button to your page that, when clicked, results in a request to the Alta Vista search engine to locate all the Web sites that link to your page (that is, to your home page backlinks).

Incidentally, you don’t have to create a button or put this information on a page. You may just want to find out how many people on the Web have linked to your home page. To do this, go to Alta Vista and enter a search for:

link:http://whatis.com

Substitute your own home page address for “whatis.com”. Alta Vista will tell you how many sites link to you and return the list so that you can find out which sites link to you. (Note that the Alta Vista list provides only those links to your site that they have currently indexed.)

backplane

A backplane is an electronic circuit board containing circuitry and sockets into which additional electronic devices on other circuit boards or **cards** can be plugged; in a computer, generally synonymous with or part of the **motherboard**.

back-pressure sensor

A back-pressure sensor is a **transducer** that detects and measures the instantaneous torque that a **robot** motor applies. The sensor produces a variable signal, usually a **voltage**, that changes in a linear manner as the torque varies.

When a robot motor operates, it encounters mechanical resistance. This resistance might depend on lifted mass, mechanical friction against a surface or within a system, or the opposition to applied force caused by electromagnetic interaction (as in an electric generator). Torque is the turning force that a robot motor delivers. It is important that a robot motor provide enough torque to overcome the resistance in external systems, but excessive torque can be destructive.

A robot motor produces a measurable back pressure that depends on the applied torque. The greater the torque, the greater the back pressure, and the greater the output of the back-pressure sensor. This output, called the back signal or back voltage, can be used in a feedback loop to reduce the torque applied by the motor. The loop configuration acts as a force limiter that minimizes the possibility of damage to objects handled by a robotic end effector. The force limiter can also reduce the chance of injury to personnel working around the robot.

Also see **end effector** and **robotics**.

backside bus

In a personal computer with an Intel **processor chipset** that includes a Dual Independent Bus (DIB), the **frontside bus** is the data path and physical interface between the processor and the main memory (**RAM**). The **backside bus** is the data path and physical interface between the processor and the **L1 and L2** memory. Both the frontside bus and the backside bus can be in use at the same time, meaning that the processor gets more done in a given number of pulses per second (see **clock speed**).

Prior to Intel's **Pentium Pro** processor, both the L2 cache and RAM were accessed using the same bus, creating an occasional bottleneck and reducing the overall **throughput** of the computer. Beginning with the Pentium Pro, the level-2 (**L2**) is packaged on the same module or **chipset** as the processor. Intel's Dual Independent Bus (DIB) design separates and coordinates accesses between the processor and RAM and accesses between the processor and the L2 cache. The frontside bus operates at 66 or 100 **MHz**, depending on the chipset. In the Pentium Pro, the backside bus (to the L2 cache) operates at the same clock speed as the processor. In the Pentium II, the backside bus operates at one-half the processor clock speed.

backup

Backup is the activity of copying **files** or **databases** so that they will be preserved in case of equipment failure or other catastrophe. Backup is usually a routine part of the operation of large businesses with **mainframes** as well as the administrators of smaller business computers. For personal computer users, backup is also necessary but often neglected. The retrieval of files you backed up is called *restoring* them.

Personal computer users can consider both local backup and Internet backup.

Local Backup

These are some options, with the least expensive approach listed first.

- Backing up critical files to diskettes. This approach is commonly used by people who keep their checkbooks and personal finance data on the computer. Programs like Quicken and Managing Your Money always remind users when they quit the program to backup their data. If your **hard disk** crashes, you'll be able to reconstruct your checkbook balances. If you have other files (for example, chapters of a book you're working on), you'll want to backup every single day's work. Copying it to a diskette is quick and economical.

- Backing up to a **Zip drive**, Jaz, Syquest, or similar hard disks. Once a week or so, you should back up your files (at least your own data files and perhaps the entire contents of your hard drive) to an alternative storage device, such as a Zip drive. These devices hold at least one million bytes on a special hard disk. Backing up usually takes a while (about 45 minutes for the contents of a 500 megabyte hard disk).
- There are also easily removable drives that you can back up to, especially if you have other reasons to use these (for example, for large graphic images that you store offline).

Internet Backup

You can also consider sending your files to another site for safekeeping. In case your hard disk crashes, you'll be able to download them from the safekeeping site. These are some products and services that are offered:

- Atrieva provides the user with a client program that allows the user to send files being backed up to an Atrieva-designated backup site. One monthly charge entitles you to back up up to 25 megabytes.
- BackupNet sells both a server and a client and is aimed at helping you set up your own **intranet**.
- QuickBackup is a client program from McAfee Associates. They have a modest charge for the client and a relatively low monthly charge for storing 30 MB. QuickBackup lets you save by folder or file types.

backward compatible

Backward compatible (or sometimes backward-compatible or backwards compatible) refers to a hardware or software system that can successfully use interfaces and data from earlier versions of the system or with other systems. For example, **Perl**, the scripting language, was designed to be backward compatible with **awk**, an earlier language that Perl was designed to replace.

Backward compatibility is more easily accomplished if the previous versions have been designed to be **forward compatible**, or **extensible**, with built-in features such as **Hooks**, **plug-in**, or an application program interface (**API**) that allows the addition of new features.

The term *backward compatible* (notice the "b") is sometimes used to describe hardware or software that is designed without regard for compatibility with earlier versions, causing the two versions to fight (or combat) each other. In this case, the two versions cannot share data easily and may have features that cause errors or crashes when they are installed on the same computer, often because the computer does not understand which version is being referred to. Even if the earlier version is removed, remaining vestiges of it may cause problems in running the newer version.

BAL

1) BAL (Basic Assembler Language) is a version of IBM's **assembler** language (sometimes called *assembly language*) for its System/360 and System/370 **mainframe operating systems**. An assembler language consists of computer **instructions** to the **processor**, each specifying a specific processor operation and input or output registers or data addresses. Most programs are written in higher-level languages. However, assembler language may be needed for programs that must run using little memory or that must execute very quickly.

2) BAL (branch-and-link) is the name of a System/360/370 assembler language instruction.

balanced scorecard methodology

Balanced scorecard methodology is an analysis technique designed to translate an organization's mission statement and overall business strategy into specific, quantifiable goals and to monitor the organization's performance in terms of achieving these goals. Developed by Robert Kaplan and David Norton in 1992, the balanced scorecard methodology is a comprehensive approach that analyzes an organization's overall performance in four ways, based on the idea that assessing performance through financial returns only provides information about how well the organization did prior to the assessment, so that future performance can be predicted and proper actions taken to create the desired future.

The methodology examines performance in four areas: financial analysis, the most traditionally used performance indicator, includes assessments of measures such as operating costs and return-on-investment; customer analysis looks at customer satisfaction and retention; internal analysis looks at production and innovation, measuring performance in terms of maximizing profit from current products and following indicators for future productivity; and finally, learning and growth analysis explores the effectiveness of management in terms of measures of employee satisfaction and retention and information system performance.

As a structure, balanced scorecard methodology breaks broad goals down successively into vision, strategies, tactical activities, and **metrics**. As an example of how the methodology might work, an organization might include in its mission statement a goal of maintaining employee satisfaction. This would be the organization's vision. Strategies for achieving that vision might include approaches such as increasing employee-management communication. Tactical activities undertaken to implement the strategy could include, for example, regularly scheduled meetings with employees. Finally, metrics could include quantifications of employee suggestions or employee surveys.

The balanced scorecard approach to management has gained popularity worldwide since the 1996 release of Norton and Kaplan's text, *The Balanced Scorecard: Translating Strategy into Action*. Kaplan has subsequently published another book on the subject, called *The Balanced Scorecard: You Can't Drive a Car Solely Relying on a Rearview Mirror*. The Gartner Group estimates that at least forty percent of all Fortune 1000 companies are now using the methodology.

balun

A balun is a device that joins a balanced line (one that has two conductors, with equal currents in opposite directions, such as a **twisted pair** cable) to an unbalanced line (one that has just one conductor and a ground, such as a **coaxial cable**). A balun is a type of transformer: it's used to convert an unbalanced signal to a balanced one or vice versa. Baluns isolate a transmission line and provide a balanced output. A typical use for a balun is in a television **antenna**. The term is derived by combining *balanced* and *unbalanced*.

In a balun, one pair of terminals is balanced, that is, the currents are equal in magnitude and opposite in phase. The other pair of terminals is unbalanced; one side is connected to electrical ground and the other carries the signal.

Balun transformers can be used between various parts of a **wireless** or cable communications system. The following table denotes some common applications.

Balanced	Unbalanced
Television receiver	Coaxial cable network
Television receiver	Coaxial antenna system
FM broadcast receiver	Coaxial antenna system
Dipole antenna	Coaxial transmission line
Parallel-wire	Coaxial transmitter output transmission line
Parallel-wire	Coaxial receiver input transmission line
Parallel-wire	Coaxial transmission line transmission line

Some baluns provide **impedance** transformation in addition to conversion between balanced and unbalanced signal modes; others provide no impedance transformation. For 1:1 baluns (no impedance transformation), the input and output are usually both 50 ohms or 75 ohms. The most common impedance-transformation ratio is 1:4 (alternatively 4:1). Some baluns provide other impedance-transformation ratios, such as 1:9 (and 9:1), 1:10 (and 10:1), or 1:16 (and 16:1). Impedance-transformer baluns having a 1:4 ratio are used between systems with impedances of 50 or 75 ohms (unbalanced) and 200 or 300 ohms (balanced). Most television and FM broadcast receivers are designed for 300-ohm balanced systems, while coaxial cables have characteristic impedances of 50 or 75 ohms. Impedance-transformer baluns with larger ratios are used to match high-impedance balanced antennas to low-impedance unbalanced wireless receivers, transmitters, or transceivers.

In order to function at optimum efficiency, a balun must be used with loads whose impedances present little or no reactance. Such impedances are called “purely resistive.” As a general rule, well-designed communications antennas present purely resistive loads of 50, 75, or 300 ohms, although a few antennas have higher resistive impedances.

The “balanced” terminals of some baluns can be connected to an unbalanced system. One terminal of the balanced pair (input or output) is connected to ground, while the other is connected to the active system element. When this is done, the device does not operate as a true balun, because both the input and the output are unbalanced. A balun used in this way has been called an “un-un” (for “unbalanced-to-unbalanced”). Some baluns can work as an impedance transformer between two unbalanced systems if there is little or no reactance. But certain types of baluns do not work properly when connected in this manner. It is best to check the documentation provided with the device, or contact the manufacturer, if “un-un” balun operation is contemplated.

band

In telecommunication, a band—sometimes called a **frequency band**—is a specific range of frequencies in the radio frequency (RF) spectrum, which is divided among ranges from *very low frequencies* (vlf) to *extremely high frequencies* (ehf). Each band has a defined upper and lower frequency limit.

Because two radio transmitters sharing the same frequency band cause mutual interference, band usage is regulated. International use of the radio spectrum is regulated by the International Telecommunication Union (ITU). Domestic use of the radio spectrum is regulated by national agencies such as the Federal Communications Commission (FCC) in the U.S. Regulatory organizations assign each transmission source a band of operation, a transmitter radiation pattern, and a maximum transmitter power.

Bands, Frequency Ranges, and Allocations:

- Very low frequencies (vlf) range from 3 to 30 kilohertz (kHz). Time signals and standard frequencies are among the users of this band.
- Low frequencies (lf) range from 30 to 300 kHz. Fixed, maritime mobile and navigational systems and radio broadcasting are among the users of this band.
- Medium frequencies (mf) range from 300 to 3000 kHz. Land, maritime mobile and radio broadcasting are among the users of this band.
- High frequencies (hf)—also called *shortwaves*—range from 3 to 30 megahertz (MHz). Fixed, mobile, aeronautical and marine mobile, amateur radio, and radio broadcasting are among the users of this band.

- Very high frequencies (vhf) range from 30 to 300 MHz. Fixed, mobile, aeronautical and marine mobile, amateur radio, television and radio broadcasting, and radio navigation are among the users of this band.
- Ultra high frequencies (uhf) range from 300 to 3000 MHz. Fixed, mobile, aeronautical and marine mobile, amateur radio, television, radio navigation and location, meteorological, and space communication are among the users of this band.
- Super high frequencies (shf) range from 3 to 30 gigahertz (GHz). Fixed, mobile, radio navigation and location, and space and satellite communication are among the users of this band.
- Extremely high frequencies (ehf) range from 30 to 300 GHz. Amateur radio, satellite, and earth and space exploration are among the users of this band.

bandpass filter

A bandpass filter is an electronic device or circuit that allows signals between two specific frequencies to pass, but that discriminates against signals at other frequencies. Some bandpass filters have amplifiers that boost the levels of signals in the accepted frequency range; these require an external source of power and are known as active bandpass filters. Other devices do not amplify and consume no power in doing their task; these are passive bandpass filters.

The illustration is an amplitude-vs-frequency graph, also called a spectral plot, of the characteristic curve of a hypothetical bandpass filter. The cutoff frequencies, f_1 and f_2 , are the frequencies at which the output signal power falls to half of its level at f_0 , the center frequency of the filter. The value $f_2 - f_1$, expressed in **hertz** (Hz), **kilohertz** (kHz), **megahertz** (MHz), or **gigahertz** (GHz), is called the filter bandwidth. The range of frequencies between f_1 and f_2 is called the filter passband.

Bandpass filters are used primarily in wireless transmitters and receivers. The main function of such a filter in a transmitter is to limit the bandwidth of the output signal to the minimum necessary to convey data at the desired speed and in the desired form. In a receiver, a bandpass filter allows signals within a selected range of frequencies to be heard or decoded, while preventing signals at unwanted frequencies from getting through. A bandpass filter also optimizes the **signal-to-noise ratio** (sensitivity) of a receiver.

In both transmitting and receiving applications, well-designed bandpass filters, having the optimum bandwidth for the mode and speed of communication being used, maximize the number of signals that can be transferred in a system, while minimizing the interference or competition among signals.

bandwidth

Bandwidth (the width of a **band** of electromagnetic frequencies) is used to mean (1) how fast **data** flows on a given transmission path, and (2), somewhat more technically, the width of the range of frequencies that an electronic **signal** occupies on a given transmission medium. Any **digital** or **analog** signal has a bandwidth.

Generally speaking, bandwidth is directly proportional to the amount of data transmitted or received per unit time. In a qualitative sense, bandwidth is proportional to the complexity of the data for a given level of system performance. For example, it takes more bandwidth to download a photograph in one second than it takes to download a page of text in one second. Large sound files, computer programs, and animated videos require still more bandwidth for acceptable system performance. Virtual reality (VR) and full-length three-dimensional audio/visual presentations require the most bandwidth of all.

In digital systems, bandwidth is expressed as data speed in bits per second (**bps**). Thus, a **modem** that works at 57,600 bps has twice the bandwidth of a modem that works at 28,800 bps. In analog systems, bandwidth is expressed in terms of the difference between the highest-frequency signal component and the lowest-frequency signal component. **Frequency** is measured in the number of cycles of change per second, or **hertz**. A typical voice signal has a bandwidth of approximately three kilohertz (3 kHz); an analog television (TV) broadcast video signal has a bandwidth of six megahertz (6 MHz)—some 2,000 times as wide as the voice signal.

Communications engineers once strove to minimize the bandwidths of all signals, while maintaining a minimum acceptable level of system performance. This was done for at least two reasons: (1) low-bandwidth signals are less susceptible to noise interference than high-bandwidth signals; and (2) low-bandwidth signals allow for a greater number of communications exchanges to take place within a specified band of frequencies. However, this simple rule no longer applies in general. For example, in **spread spectrum** communications, the bandwidths of signals are deliberately expanded. In digital cable and fiber optic systems, the demand for ever-increasing data speeds outweighs the need for bandwidth conservation. In the **electromagnetic radiation spectrum**, there is only so much available bandwidth to go around, but in hard-wired systems, available bandwidth can literally be constructed without limit by installing more and more cables.

bandwidth test

A bandwidth test is a program that sends one or more files of known size over a network to a distant computer (for example, your own computer), measures the time required for the file(s) to successfully download at the destination, and thereby obtains a theoretical figure for the data speed between two or more points, usually in kilobits per second (**Kbps**) or megabits per second (**Mbps**).

Bandwidth test results vary greatly, even from moment to moment, and occasionally produce absurd or improbable figures. Factors that affect test results include:

- Internet traffic (speed generally decreases as volume increases)
- Variable propagation delays (can artificially inflate or degrade the result)
- Noise on data lines (has a real detrimental effect)
- The size(s) of file(s) used for the test
- The number of files used for the test
- The demand load on the test server at time of test
- Geomagnetic and/or thunderstorm activity

In order to get a reasonable estimate of **bandwidth** (sometimes referred to as **throughput**), experts suggest that three or more different test sites be used, and that each test be conducted six times at each site. Then the top and bottom $\frac{1}{3}$ of the figures should be disregarded. Finally, the middle $\frac{1}{3}$ of the results should be averaged.

banner

Depending on how it's used, a banner is either a graphic image that announces the name or identity of a site (and often is spread across the width of the Web page) or is an advertising image. Advertisers sometimes count banner "views," or the number of times a banner graphic image was downloaded over a period of time.

bar code

A bar code (often seen as a single word, *barcode*) is the small image of lines (bars) and spaces that is affixed to retail store items, identification cards, and postal mail to identify a particular product number, person, or location. The code uses a sequence of vertical bars and spaces to represent numbers and other symbols. A bar code reader is used to read the code. The reader uses a laser beam that is sensitive to the reflections from the line and space thickness and variation. The reader translates the reflected light into digital data that is transferred to a computer for immediate action or storage. Bar codes and readers are most often seen in supermarkets and retail stores, but a large number of different uses have been found for them. They are also used to take inventory in retail stores; to check out books from a library; to track manufacturing and shipping movement; to sign in on a job; to identify hospital patients; and to tabulate the results of direct mail marketing returns. Very small bar codes have been used to tag honey bees used in research. Readers may be attached to a computer (as they often are in retail store settings) or separate and portable, in which case they store the data they read until it can be fed into a computer.

There is no one standard bar code; instead, there are several different bar code standards that serve different uses, industries, or geographic needs. Since 1973, the Uniform Product Code (UPC), regulated by the Uniform Code Council, an industry organization, has provided a standard bar code used by most retail stores. The European Article Numbering system (EAN), developed by Joe Woodland, the inventor of the first bar code system, allows for an extra pair of digits and is becoming widely used. POSTNET is the standard bar code used in the United States for ZIP codes in bulk mailing. The following table summarizes the most common bar code standards.

Bar Code Standard	Uses
Uniform Product Code (UPC)	Retail stores for sales checkout; inventory, etc.
Code 39 (Code 3 of 9)	Identification, inventory, and tracking shipments
POSTNET	Encoding zip codes on U.S. mail
European Article Number (EAN)	A superset of the UPC that allows extra digits for country identification

Bar Code Standard	Uses
Japanese Article Number (JAN)	Similar to the EAN, used in Japan
Bookland	Based on ISBN numbers and used on book covers
ISSN bar code	Based on ISSN numbers, used on periodicals outside the U.S.
Code 128	Used in preference to Code 39 because it is more compact
Interleaved 2 of 5	Used in the shipping and warehouse industries
Codabar	Used by Federal Express, in libraries, and blood banks
MICR (Magnetic Ink Character Recognition)	A special font used for the numbers on the bottom of bank checks
OCR-A	The optical character recognition format used on book covers for the human readable version of the ISBN number
OCR-B	Used for the human readable version of the UPC, EAN, JAN, Bookland, and ISSN bar codes and for optional human-readable digits with Code 39 and Interleaved 2 of 5 symbols
Maxicode	Used by the United Parcel Service
PDF417	A new 2-D type of bar code that can encode up to 1108 bytes of information; can become a compressed, portable data file (which is what the "PDF" stands for)

bar

In programming, bar is a **metasyntactic variable** that is used to temporarily represent a **function**. Other examples include (but are by no means limited to) ack, baz, blarg, wibble, **foo**, fum, and qux. Metasyntactic variables are sometimes used in developing a conceptual version of a program or examples of programming code written for illustrative purposes.

Any filename beginning with a metasyntactic variable denotes a scratch file. This means the file can be deleted at any time without affecting the program.

When two or more metasyntactic variables are needed, *bar* is often paired with *foo* as a result of the fact that foo is phonetically the first part of the otherwise unrelated acronym, **FUBAR**. In other words, foo (which has its own history; see Smokey Stover) gave rise to the later use of bar as a metasyntactic variable because of its phonetic association with the well-known acronym.

Sometimes the terms Base Address Register and Buffer Address Register are shortened to the acronym bar or BAR.

In physics, the bar is a unit of pressure equal to one million (10^6) dynes, equivalent to 10 newtons, per square centimeter. This is approximately the pressure exerted by Earth's atmosphere at sea level.

Also see **foo** and **FUBAR**.

baseband

Also see **band**, **bandwidth**, **broadband**, and **narrowband**.

Baseband has several usages:

- 1) Describing a telecommunication system in which information is carried in digital form on a single unmultiplexed signal channel on the transmission medium. This usage pertains to a **baseband network** such as **Ethernet** and **token ring local area networks**.
- 2) Same as the above, but allowing that the information could also be carried in analog form.
- 3) Any frequency **band** on which information is superimposed, whether or not the band is multiplexed and information is sent on subbands. In this usage, there is sometimes the meaning that the frequency band is not shifted to some other frequency band but remains at its original place in the electromagnetic spectrum.

BASIC

BASIC was an early programming language that is still among the most popular programming languages. Originally designed as an interactive **mainframe** timesharing language by John Kemeny and Thomas Kurtz in 1963, it became widely used on personal computers everywhere. On IBM's first "family" computer, the PCjr, a BASIC cartridge was a popular add-on. Because of its simplicity, BASIC has frequently been used in teaching the introductory concepts of programming with a working language.

BASIC continues to be widely used because it can be learned quickly, its statements are easy to read by other programmers, and support is available on most operating systems. BASIC's documentation has been translated into many national languages. It often comes with sound and graphics support. A popular version of BASIC today is QBASIC.

BASIC is used in many business applications and is still considered a valid choice as a programming language for some purposes. Microsoft's **Visual Basic** adds object-oriented features and a graphical user interface to the standard BASIC.

The following example of BASIC gets a number from a user, multiplies the number by 10, and prints or displays the result:

```
10 PRINT 'Enter a number'
20 INPUT NUM
30 PRINT 'Your number * 10 is ';NUM*10;
```

basic input/output system

See "BIOS"

Basic Rate Interface

In the Integrated Services Digital Network (**ISDN**), there are two levels of service: the Basic Rate Interface (**BRI**), intended for the home and small enterprise, and the Primary Rate Interface (**PRI**), for larger users. Both rates include a number of B-channels and a D-channel. Each **B-channel** carries data, voice, and other services. The **D-channel** carries control and signaling information.

The Basic Rate Interface consists of two 64 Kbps B-channels and one 16 Kbps D-channel. Thus, a Basic Rate Interface user can have up to 128 Kbps service. The Primary Rate Interface consists of 23 B-channels and one 64 Kbps D-channel in the United States or 30 B-channels and 1 D-channel in Europe.

For more information, see **ISDN**.

bastion host

On the Internet, a bastion host is the only **host** computer that a company allows to be addressed directly from the public network and that is designed to screen the rest of its network from security exposure.

batch

In a computer, a batch job is a program that is assigned to the computer to run without further user interaction. Examples of batch jobs in a PC are a printing request or an analysis of a Web site log. In larger commercial computers or servers, batch jobs are usually initiated by a system user. Some are defined to run automatically at a certain time.

In some computer systems, batch jobs are said to run in the background and interactive programs run in the foreground. In general, interactive programs are given priority over batch programs, which run during the time intervals when the interactive programs are waiting for user requests.

The term originated when punched cards were the usual form of computer input and you put a batch of cards (one batch per program) in a box in the sequence that they were to be fed into the computer by the computer operator. (Hopefully, you got the output back the next morning.)

batch file

A batch file is a text **file** that contains a sequence of commands for a computer **operating system**. It's called a batch file because it batches (bundles or packages) into a single file a set of commands that would otherwise have to be presented to the system interactively from a keyboard one at a time. A batch file is usually created for command sequences for which a user has a repeated need. Commonly needed batch files are often delivered as part of an operating system. You initiate the sequence of commands in the batch file by simply entering the name of the batch file on a command line.

In the **Disk Operating System** (DOS), a batch file has the file name extension ".BAT". (The best known DOS batch file is the AUTOEXEC.BAT file that initializes DOS when you start the system.) In UNIX-based operating systems, a batch file is called a **shell script**. In IBM's mainframe VM operating systems, it's called an EXEC.

battery

A battery is an electrochemical cell (or enclosed and protected material) that can be charged electrically to provide a static potential for power or released electrical charge when needed.

A battery generally consists of an *anode*, a *cathode*, and an *electrolyte*.

Common types of commercial batteries and some of their characteristics and advantages are summarized in the following table. Battery types not shown include the Zinc-Air, Flooded Lead Acid, and Alkaline batteries.

Battery Type	Characteristics	Typical Uses	Advantages
Sealed Lead Acid (SLA) battery	Can hold a charge for up to 3 years	Backup emergency power source	Inexpensive
Nickel-Cadmium (Ni-Cd) battery	Fast, even energy discharge	Appliances, audio and video equipment, toys; most popular battery	Relatively inexpensive; widely available
Nickel-Metal Hydride (Ni-MH) battery	Typical power capacity 1.2 V—1200 to 1500 mAh; extended life 2300 mAh; 2.5 to 4 hours battery life	Portable computers; cellular phones; same as for Ni-Cd batteries	No memory effect; unused capacity remains usable
Lithium Ion (Li-Ion) battery	Stable and safe; highest energy capacity	Portable computers; cellular phones; same as for Ni-Cd batteries	Twice the charge capacity of Ni-Cd; slow self-discharge

baud

Baud was the prevalent measure for data transmission speed until replaced by a more accurate term, **bps** (bits per second). One baud is one electronic state change per second. Since a single state change can involve more than a single bit of data, the bps unit of measurement has replaced it as a better expression of data transmission speed.

The measure was named after a French engineer, Jean-Maurice-Emile Baudot. It was first used to measure the speed of telegraph transmissions.

Bayesian logic

Named for Thomas Bayes, an English clergyman and mathematician, Bayesian logic is a branch of logic applied to decision making and inferential statistics that deals with **probability** inference: using the knowledge of prior events to predict future events. Bayes first proposed his theorem in his 1763 work (published two years after his death in 1761), *An Essay Towards Solving a Problem in the Doctrine of Chances*. Bayes' theorem provided, for the first time, a mathematical method that could be used to calculate, given occurrences in prior trials, the likelihood of a target occurrence in future trials. According to Bayesian logic, the only way to quantify a situation with an uncertain outcome is through determining its probability. Bayes' Theorem is a means of quantifying uncertainty.

Based on probability theory, the theorem defines a rule for refining an hypothesis by factoring in additional evidence and background information, and leads to a number representing the degree of probability that the hypothesis is true. To demonstrate an application of Bayes' Theorem, suppose that we have a covered basket that contains three balls, each of which may be green or red. In a blind test, we reach in and pull out a red ball. We return the ball to the basket and try again, again pulling out a red ball. Once more, we return the ball to the basket and pull a ball out—red again. We form a hypothesis that all the balls are all, in fact, red. Bayes' Theorem can be used to calculate the probability (p) that all the balls are red (an event labeled as "A") given (symbolized as "I") that all the selections have been red (an event labeled as "B"):

$$p(A|B) = p(A + B)/p\{B\}$$

Of all the possible combinations (RRR, RRG, RGG, GGG), the chance that all the balls are red is $1/4$; in $1/8$ of all possible outcomes, all the balls are red AND all the selections are red. Bayes' Theorem calculates the probability that all the balls in the basket are red, given that all the selections have been red as .5 (probabilities are expressed as numbers between 0. and 1., with "1." indicating 100% probability and "0." indicating zero probability).

The International Society for Bayesian Analysis (ISBA) was founded in 1992 with the purpose of promoting the application of Bayesian methods to problems in diverse industries and government, as well as throughout the Sciences. The modern incarnation of Bayesian logic has evolved beyond Bayes' initial theorem, developed further by the 18th century French theorist Pierre-Simon de Laplace, and 20th and 21st century practitioners such as Edwin Jaynes, Larry Bretthorst, and Tom Lored. Current and possible applications of Bayesian logic include an almost infinite range of research areas, including genetics, astrophysics, psychology, sociology, artificial intelligence (AI), data mining, and computer programming.

BBS

See "bulletin board system"

Bcc

In Eudora and perhaps other e-mail facilities, you'll see the abbreviations "Fcc" and "Bcc". "Fcc" is the same as "cc" or **carbon copy**—that is: Send a copy of the message to the address you fill in. "Bcc" stands for "Blind carbon copy" which says: Send a copy to another address...but in this case, don't indicate to the Fcc recipient that you also sent this copy.

B-channel

In the Integrated Services Digital Network (ISDN), the B-channel is the channel that carries the main data. (The "B" stands for "bearer" channel.)

In ISDN, there are two levels of service: the Basic Rate Interface, intended for the home and small enterprise, and the Primary Rate Interface, for larger users. Both rates include a number of B- (bearer) channels and a **D-channel**. The B-channels carry data, voice, and other services. The D-channel carries control and signaling information.

The Basic Rate Interface consists of two 64 Kbps B-channels and one 16 Kbps D-channel. Thus, a Basic Rate Interface user can have up to 128 Kbps service. The Primary Rate Interface consists of 23 B-channels and one 64 Kbps D-channel in the United States or 30 B-channels and 1 D-channel in Europe.

Bean

In its **JavaBeans** application program interface for writing a component, Sun Microsystems calls a component a "Bean" (thus continuing their coffee analogy). A Bean is simply the Sun Microsystems variation on the idea of a component.

In **object-oriented programming** and **distributed** object technology, a component is a reusable program building block that can be combined with other components in the same or other computers in a distributed network to form an application. Examples of a component include: a single button in a graphical user interface, a small interest calculator, an interface to a database manager. Components can be deployed on different servers in a network and communicate with each other for needed services. A component runs within a context called a **container**. Examples of containers include pages on a Web site, Web browsers, and word processors.

becquerel

The becquerel is the derived unit of radioactivity in the International System of Units (SI), symbolized Bq and equal to one disintegration or nuclear transformation per second. Reduced to base SI units, 1 Bq = 1 s⁻¹. The becquerel is named after Antoine Henri Becquerel, the French physicist credited with the discovery of radioactivity. In the 1970s, the becquerel replaced the curie as the standard unit of radioactivity.

The becquerel is a small unit. In practical situations, radioactivity is often quantified in kilobecquerels (kBq) or megabecquerels (MBq), where:

$$1 \text{ kBq} = 1000 \text{ Bq} = 10^3 \text{ Bq}$$

$$1 \text{ MBq} = 1000 \text{ kBq} = 1,000,000 \text{ Bq} = 10^6 \text{ Bq}$$

Thus, 1 kBq is the equivalent of 1000 disintegrations per second (10³ s⁻¹), or an average of one disintegration per millisecond, and 1 MBq is the equivalent of 1,000,000 disintegrations per second (10⁶ s⁻¹), or an average of one disintegration per microsecond.

Also see International System of Units (SI).

BEDO DRAM

BEDO DRAM (Burst Extended Data Output DRAM) is a type of dynamic random access memory (**DRAM**) that can send data back to the computer from one read operation at the same time it is reading in the address of the next data to be sent. In addition, after reading the address, it is able to send the data back in three successive clock cycles without clock coordination (that is, the three successive outputs seem to be sent from the RAM in a sudden **burst**). It works well with microprocessors that operate up to 66 MHz.

BEDO DRAM and various types of **SDRAM** are two recent RAM technologies that are being incorporated in newer computers.

beep code

A beep code is the audio signal given out by a computer to announce the result of a short diagnostic testing sequence the computer performs when first powering up (called the Power-On-Self-Test or **POST**). The POST is a small program contained in the computer's basic input/output operating system (**BIOS**) that checks to make sure necessary hardware is present and required memory is accessible. If everything tests out correctly, the computer will typically emit a single beep and continue the starting-up process. If something is wrong, the computer will display an error message on the monitor screen and announce the errors audibly with a series of beeps that vary in pitch, number and duration (this is especially useful when the error exists with the monitor or graphic components). The beeping sequence is really a coded message (beep code) designed to tell the user what is wrong with the computer.

There is no official standard for beep codes; audio patterns vary according to the manufacturer of the computer's BIOS program. If an error message is beeped on startup, the user must first determine what kind of BIOS the computer is running (Phoenix or AMI are the most popular) and use that information to look up the particular beep code sequence that is being sent. BIOS information and beep code interpretations can be found in the manual that comes with the computer and on the manufacturer's Web site.

Beginners All-Purpose Symbolic Instruction Code

See "BASIC"

Bell Communications Research

See "Bellcore"

Bell operating company

See "BOC"

Bellcore

Bellcore (Bell Communications Research) provides certain centralized research and standards coordination for the regional Bell operating companies (**RBOC**s). It also coordinates security and emergency preparedness for the U.S. government. Bellcore was formed in 1984 when AT&T was broken up into the seven RBOCs. Bellcore's budget comes from the RBOCs. Bellcore coordinated the design for the Advanced Intelligent Network (**AIN**).

benchmark

A benchmark is a point of reference by which something can be measured. In surveying, a "bench mark" (two words) is a post or other permanent mark established at a known elevation that is used as the basis for measuring the elevation of other topographical points.

In computer and Internet technology, the term may have any of these meanings:

- 1) A set of conditions against which a product or system is measured. PC magazine laboratories frequently test and compare several new computers or computer devices against the same set of application programs, user interactions, and contextual situations. The total context against which all products are measured and compared is referred to as the benchmark.
- 2) A program that is specially designed to provide measurements for a particular operating system or application.
- 3) A known product with which users are familiar or accustomed to that other newer products can be compared to.
- 4) A set of performance criteria which a product is expected to meet.

Laboratory benchmarks sometimes fail to reflect real-world product use. For this reason, Eric Raymond defines a benchmark as "an inaccurate measure of computer performance" and cites the "old hacker's saying" that "In the computer industry, there are three kinds of lies: lies, damn lies, and benchmarks."

Still, benchmarks can be useful. If you'd like to try one out yourself on your own operating system, browser, file server, or notebook battery life, the ZDNet Testing Labs site offers downloads of popular benchmark programs.

BeOS

BeOS is a personal computer **operating system** that its makers describe as designed for the multimedia applications of the future. Be founder Jean-Louis Gasse left Apple Computer in 1990 to create an operating system that could exploit new architectural ideas and be free of the baggage that older operating systems invariably bring with them. The first BeOS was used in a computer called the BeBox, since

abandoned so the company could concentrate on the software. In 1996, BeOS had Apple's **Macintosh** users in mind when it ported the system to the **PowerPC microprocessor**. More recently, BeOS has been ported to Intel's **Pentium** computers. It can be installed in the same computer with another operating system such as Windows or Mac OS and used as an alternative operating system for applications requiring fast handling of streaming video, games, and other multimedia applications.

BeOS can run on multiple microprocessors at the same time (using **symmetric multiprocessing**) and is able to coordinate work threads across the processors. Anticipating the arrival of **digital versatile disk** and very large files such as feature-length movies, BeOS provides a 64-bit file system that can handle files of **terabyte** size. The operating system, say the BeOS makers, no longer has to be a bottleneck between the Internet, applications, and the user.

BeOS comes with a **desktop** user interface that improves in some ways on both Windows and the Mac and a built-in Web browser, audio, **MIDI**, and its own 3D interface as well as support for **OpenGL**. Other features include **antialiasing** fonts, **Unicode**, and support for **POSIX** utilities and shell commands.

BeOS is also sold as a good system to develop programs for. Programmers are given a relatively simple **object-oriented programming application program interface**. Metrowerks provides **C++** and **Java** development environments. Because BeOS has little legacy baggage to carry, its system is seen as simpler, easier to maintain and evolve, and less prone to failure. The industry assessment, however, is that without a **killer app**, BeOS faces an uphill battle. Meanwhile, a number of games are in development and Beatware has developed an office suite (Writer, Sum-It, and Get-It) for it.

Beowulf

Beowulf is an approach to building a **supercomputer** as a *cluster* of commodity off-the-shelf personal computers, interconnected with a technology like **Ethernet**, and running programs written for **parallel processing**. The Beowulf idea is said to enable the average university computer science department or small research company to build its own small supercomputer that can operate in the **gigaflop** (billions of operations per second) range. In addition to possible cost savings, building your own supercomputer is said to be a learning investment and make you less dependent in the future on particular hardware and software vendors. As off-the-shelf technology evolves, a Beowulf can be upgraded to take advantage of it.

The original Beowulf cluster was developed in 1994 at the Center of Excellence in Space Data and Information Sciences (CESDIS), a contractor to the US National Aeronautics and Space Administration (NASA) at the Goddard Space Flight Center in Greenbelt, Maryland. Thomas Sterling and Don Becker built a cluster computer that consisted of 16 Intel DX4 **processors** connected by channel-bonded 10 **Mbps Ethernet**.

Their success led to the Beowulf Project, which fosters the development of similar commodity off-the-shelf (COTS) clusters. A number have been developed in universities and research groups, ranging from the original 16-processor Beowulf to Avalon, a cluster of 140 **Alpha** processors built by the Los Alamos National Laboratory. A more typical smaller cluster might have 16 200-MHz (or faster) Intel P6 processors connected by **Fast Ethernet** and a Fast Ethernet switch.

As a way to lower cost and increase vendor independency, Beowulf developers often choose the **Linux** operating system and use standard message passing **protocols** between the computers within the cluster. A Beowulf cluster is placed in the taxonomy of parallel computing as somewhere below a massively parallel processor (**MPP**) and a network of workstations (**NOW**) that is clustered for the purpose of load-balancing.

BER

See "bit error rate"

bespoke

Bespoke (pronounced bee-SPOHK) is a term used in the United Kingdom and elsewhere for an individually- or custom-made product or service. Traditionally applied to custom-tailored clothing, the term has been extended to information technology, especially for software consulting services. Typically, software consulting companies offer packaged (already invented and generally applicable) software and bespoke software for client needs that can't be satisfied by packaged software. In the U.S., bespoke software is often called custom or custom-designed software.

Bespoke is a form derived from *bespeak*, which was used as early as 1583 to refer to the ordering of goods.

best practice

A best practice is a technique or methodology that, through experience and research, has proven to reliably lead to a desired result. A commitment to using the best practices in any field is a commitment to using all the knowledge and technology at one's disposal to ensure success. The term is used frequently in the fields of health care, government administration, the education system, project management, hardware and software product development, and elsewhere.

In software development, a best practice is a well-defined method that contributes to a successful step in product development. Throughout the software industry, several best practices are widely followed. Some of the more commonly used are: an iterative development process, requirement management, quality control, and change control.

An iterative (meaning repetitive) development process, which progresses in incremental stages, helps to maintain a focus on manageable tasks and ensures that earlier stages are successful before the later stages are attempted. Requirement management addresses the problem of creeping requirements, which is a situation in which the client requests additional changes to the product that are beyond the scope of what was originally planned. To guard against this common phenomenon, requirement management employs strategies such as documentation of requirements, sign-offs, and methodologies such as the **use case**. Quality control is a strategy that defines objective measures for assessing quality throughout the development process in terms of the product's **functionality**, reliability, and performance. Change control is a strategy that seeks to closely monitor change throughout the iterative process to ensure that records are intact for changes that have been made and that unacceptable changes are not undertaken.

A best practice tends to spread throughout a field or industry after a success has been demonstrated. However, it is often noted that demonstrated best practices can be slow to spread, even within an organization. According to the American Productivity & Quality Center, the three main barriers to adoption of a best practice are a lack of knowledge about current best practices, a lack of motivation to make changes involved in their adoption, and a lack of knowledge and skills required to do so.

beta test

In software development, a beta test is the second phase of software testing in which a sampling of the intended audience tries the product out. (Beta is the second letter of the Greek alphabet.) Originally, the term *alpha test* meant the first phase of testing in a software development process. The first phase includes unit testing, component testing, and system testing. Beta testing can be considered "pre-release testing." Beta test versions of software are now distributed to a wide audience on the Web partly to give the program a "real-world" test and partly to provide a preview of the next release.

BetterWhois

BetterWhois, named after the original **whois**, lets you look up registration information from all Internet **domain name** registrars at the same time. BetterWhois is located at the BetterWhois.com Web site.

In the past, the whois facility provided the way for anyone to find out whether a domain name had been taken and, if so, the name of the company who had reserved or paid for it. whois is maintained by Network Solutions, the original .com, .org, and .net registrar on the Internet. Network Solutions has a contract with the U.S. Commerce Department and, until recently, has been the sole registrar in these domains. Recently, however, the newly-formed Internet Corporation for Assigned Names and Numbers

(ICANN) has opened the service of domain name registration in these domains to other companies. While Network Solutions continues to be the largest registrar, at least six new companies are now offering similar services, and scores of companies are expected to be offering registration services in the near future.

BetterWhois lets you search the registration databases of all the accredited registrars in a single search. They also provide a linked list of all the registrars and allow a user to receive the detailed domain report by e-mail.

BGP

BGP (Border Gateway Protocol) is a **protocol** for exchanging routing information between **gateway hosts** (each with its own **router**) in a network of **autonomous systems**. BGP is often the protocol used between gateway hosts on the Internet. The routing table contains a list of known routers, the addresses they can reach, and a cost **metric** associated with the path to each router so that the best available route is chosen.

Hosts using BGP communicate using the Transmission Control Protocol (TCP) and send updated router table information only when one host has detected a change. Only the affected part of the routing table is sent. BGP-4, the latest version, lets administrators configure cost metrics based on policy statements. (BGP-4 is sometimes called BGP4, without the hyphen.)

BGP communicates with autonomous (local) networks using Internal BGP (IBGP) since it doesn't work well with IGP. The routers inside the autonomous network thus maintain two routing tables: one for the interior gateway protocol and one for IBGP.

BGP-4 makes it easy to use Classless Inter-Domain Routing (CIDR), which is a way to have more addresses within the network than with the current **IP address** assignment scheme.

BGP is a more recent protocol than the Exterior Gateway Protocol (EGP).

Also see the Interior Gateway Protocol (IGP) and the Open Shortest Path First (OSPF) interior gateway protocol.

Big Blue

Big Blue refers to IBM, which has used blue as a branding color in its logo and elsewhere.

Big Chief tablet

The Big Chief tablet was for many years the most popular brand of paper writing tablet among school children and hopeful novelists in the U.S. and exemplified the lined writing tablet as a communications medium. The tablet featured a native American with full headdress on the cover. The Big Chief Writing Tablet copyright was originally held by William Albrecht at the Western Tablet Company in St.

Joseph, Missouri, and was later sold to the Mead Corporation, which also manufactured a Son of Big Chief tablet.

On January 5, 2001, the Everett Pad and Paper purchased the latest makers of the tablet, Springfield Tablet, and closed the plant after 80 years. At present, the Big Chief tablet is no longer being made. However, the lined writing tablet is likely to remain a useful artifact of information technology for many years to come even as its electronic counterpart (see Microsoft's **Tablet PC**) gains popularity.

big-endian and little-endian

Big-endian and little-endian are terms that describe the order in which a sequence of **bytes** are stored in computer memory. Big-endian is an order in which the "big end" (most significant value in the sequence) is stored first (at the lowest storage address). Little-endian is an order in which the "little end" (least significant value in the sequence) is stored first. For example, in a big-endian computer, the two bytes required for the **hexadecimal** number 4F52 would be stored as 4F52 in storage (if 4F is stored at storage address 1000, for example, 52 will be at address 1001). In a little-endian system, it would be stored as 524F (52 at address 1000, 4F at 1001).

IBM's 370 computers, most **RISC**-based computers, and Motorola microprocessors use the big-endian approach. For people who use languages that read left-to-right, this seems like the natural way to think of a storing a string of characters or numbers—in the same order you expect to see it presented to you. Many of us would thus think of big-endian as storing something in *forward* fashion, just as we read.

On the other hand, Intel **processors** (CPUs) and DEC Alphas and at least some programs that run on them are little-endian. An argument for little-endian order is that as you increase a numeric value, you may need to add digits to the left (a higher non-exponential number has more digits). Thus, an addition of two numbers often requires moving all the digits of a big-endian ordered number in storage, moving everything to the right. In a number stored in little-endian fashion, the least significant bytes can stay where they are and new digits can be added to the right at a higher address. This means that some computer operations may be simpler and faster to perform.

Language **compilers** such as that of **Java** or **FORTRAN** have to know which way the object code they develop is going to be stored. Converters can be used to change one kind of endian to the other when necessary.

Note that within both big-endian and little-endian byte orders, the bits within each byte are big-endian. That is, there is no attempt to be big- or little-endian about the entire bit stream represented by a given number of stored bytes. For example, whether hexadecimal 4F is put in storage first or last with other bytes in a given storage address range, the

bit order within the byte will be:

01001111

It is *possible* to be big-endian or little-endian about the bit order, but CPUs and programs are almost always designed for a big-endian bit order. In data transmission, however, it is possible to have either bit order.

Eric Raymond observes that Internet **domain name** addresses and e-mail addresses are little-endian. For example, a big-endian version of our domain name address would be:

com.whatis.www

Big-endian and little-endian derive from Jonathan Swift's *Gulliver's Travels* in which the Big Endians were a political faction that broke their eggs at the large end ("the primitive way") and rebelled against the Lilliputian King who required his subjects (the Little Endians) to break their eggs at the small end.

binary

Binary describes a numbering scheme in which there are only two possible values for each digit: 0 and 1. The term also refers to any **digital** encoding/decoding system in which there are exactly two possible states. In digital data memory, storage, processing, and communications, the 0 and 1 values are sometimes called "low" and "high," respectively.

Binary numbers look strange when they are written out directly. This is because the digits' weight increases by powers of 2, rather than by powers of 10. In a digital numeral, the digit furthest to the right is the "ones" digit; the next digit to the left is the "twos" digit; next comes the "fours" digit, then the "eights" digit, then the "16s" digit, then the "32s" digit, and so on. The decimal equivalent of a binary number can be found by summing all the digits. For example, the binary 10101 is equivalent to the decimal $1 + 4 + 16 = 21$:

DECIMAL = 21 64 32 16 8 4 2 1

BINARY = 10101 0 0 1 0 1 0 1

The numbers from decimal 0 through 15 in decimal, binary, **octal**, and **hexadecimal** form are listed below.

DECIMAL	BINARY	OCTAL	HEXA-DECIMAL
0	0	0	0
1	1	1	1
2	10	2	2
3	11	3	3
4	100	4	4
5	101	5	5
6	110	6	6
7	111	7	7
8	1000	10	8
9	1001	11	9
10	1010	12	A
11	1011	13	B

DECIMAL	BINARY	OCTAL	HEXA-DECIMAL
12	1100	14	C
13	1101	15	D
14	1110	16	E
15	1111	17	F

binary 8-zero substitution

See “B8ZS”

binary digit

See “bit”

binary file

A binary file is a **file** whose content must be interpreted by a program or a hardware processor that understands in advance exactly how it is formatted. That is, the file is not in any externally identifiable format so that any program that wanted to could look for certain data at a certain place within the file. A program (or hardware processor) has to know exactly how the data inside the file is laid out to make use of the file.

In general, **executable** (ready-to-run) programs are often identified as binary files and given a file name extension of “.bin”. Programmers often talk about an executable program as a “binary” and will ask another programmer to “send me the binaries.” (A synonym for this usage is **object code**.) A binary file could also contain data ready to be used by a program.

In terms of transmitting files from one place to another, a file can be transmitted as a “binary,” meaning that the programs handling it don’t attempt to look within it or change it, but just pass it along as a “chunk of 0s and 1s,” the meaning of which is unknown to any network device.

binary large object

See “BLOB”

Binary Runtime Environment for Wireless

See “BREW”

binary search

A binary search, also called a dichotomizing search, is a digital scheme for locating a specific object in a large set. Each object in the set is given a key. The number of keys is always a power of 2. If there are 32 items in a list, for example, they might be numbered 0 through 31 (binary 00000 through 11111). If there are, say, only 29 items, they can be numbered 0 through 28 (binary 00000 through 11100), with the numbers 29 through 31 (binary 11101, 11110, and 11111) as dummy keys.

To conduct the search, the keys are listed in tabular form. The position of the desired object is compared with the halfway point in the list (which lies between the two keys in the center of the list). If the key of the desired object is smaller than the halfway point value, then the first half of the list is accepted and the second half is rejected. If the key of the desired object is larger than the halfway point value, then the second half of the list is accepted and the first half is rejected. The process is repeated, each time selecting half of the list and rejecting the other half, until only one object remains. This is the desired object.

The following list shows an example of a binary search to choose the fifth object in a set of 13 objects. Keys are denoted X; the desired key is denoted by +. Dummy keys are denoted O.

XXXX+XXXXXXXXXOOO	(initial list)
XXXX+XXX	(first half accepted)
+XXX	(second half accepted)
+X	(first half accepted)
+	(first half accepted)

binary tree

A binary tree is a method of placing and locating files (called records or keys) in a **database**, especially when all the data is known to be in random access memory (**RAM**). The **algorithm** finds data by repeatedly dividing the number of ultimately accessible records in half until only one remains.

In a tree, records are stored in locations called leaves. This name derives from the fact that records always exist at end points; there is nothing beyond them. Branch points are called nodes. The order of a tree is the number of branches (called children) per node. In a binary tree, there are always two children per node, so the order is 2. The number of leaves in a binary tree is always a power of 2. The number of access operations required to reach the desired record is called the depth of the tree. The image below shows a binary tree for locating a particular record among seven records in a set of eight leaves. The depth of this tree is 4.

In a practical tree, there can be thousands, millions, or billions of records. Not all leaves necessarily contain a record, but more than half do. A leaf that does not contain a record is called a null. In the example shown here, the eighth leaf is a null, indicated by an open circle.

Binary trees are used when all the data is in random-access memory (RAM). The search algorithm is simple, but it does not minimize the number of database accesses required to reach a desired record. When the entire tree is contained in RAM, which is a fast-read, fast-write medium, the number of required accesses is of little concern. But when some or all of the data is on disk, which is slow-read, slow-write, it is advantageous to minimize the number of accesses (the tree depth). Alternative algorithms such as the **B-tree** accomplish this.

Also see **binary search** and **tree structure**. Compare **B-tree**, **M-tree**, **splay tree**, and **X-tree**.

bind

In computer programming, to bind is to make an association between two or more programming objects or value items for some scope of time and place. Here are some usages:

- 1) In general, when a program is compiled, to bind is to substitute a real for a variable value in the program or to ensure that additional programming will be loaded into storage along with the compiled program.
- 2) When a server application is started, it issues a bind request to **TCP/IP** to indicate that it is ready to listen to (receive) client application requests from the Internet that are associated with a specified **IP address**. (Using the **C** programming language, the request is specified in a *bind()* function request.)
- 3) In IBM's Systems Network Architecture (**SNA**), to bind is to set up a session between two *logical units (LUs)* or network end points prior to communicating.
- 4) In using Remote Procedure Call (**RPC**), to bind is to locate the remote server application to which a client application can make requests. This is often done by accessing a centrally-maintained directory of the names of accessible network server applications.
- 5) An earlier program that did "binding" so that different programs that called each other knew each other's addresses in memory was called a *linkage editor*.

BinHex

BinHex is a utility for converting (encoding) Macintosh files into files that will travel well on networks either as files or e-mail attachments. Like **Uencode**, BinHex encodes a file from its 8-bit binary or bit-stream representation into a 7-bit **ASCII** set of text characters. The recipient must decode it at the other end. Older e-mail utilities sometimes can't handle binary transmissions so text encoding ensures that a transmission will get to an older system. BinHex specifically

handles both resource and data forks in Macintosh files (which Uencode doesn't). BinHex files have a suffix of ".hqx". (Earlier versions have the suffix ".hex".)

Netscape and possibly other Web browsers as well as some popular e-mail applications (including Eudora) include BinHex encoding and decoding capability. Otherwise, you can download a BinHex utility for use either the Macintosh, Windows, or other systems. (In Eudora, when writing a note you want to be transmitted in BinHex, look for the little box set to a default of "MIME" and change it to "BinHex.")

biochip

A biochip is a glass or silicon wafer that is designed for the purpose of accelerating genetic research. It may also be able to rapidly detect chemical agents used in biological warfare so that defensive measures can be taken. A biochip is designed to "freeze" into place the structures of many short strands of DNA (deoxyribonucleic acid), the basic chemical instruction that determines the characteristics of an organism. Effectively, it is used as a kind of "test tube" for real chemical samples. A specially designed microscope can determine where the sample hybridized with DNA strands in the biochip.

Biochips helped to dramatically accelerate the identification of the estimated 80,000 genes in human DNA, an ongoing world-wide research collaboration known as the **Human Genome Project**. The microchip is described as a sort of word search function that can quickly sequence DNA.

Researchers believe another important use for the biochip would be to quickly identify chemical warfare agents. Known chemical agents could be immobilized on the biochips so that real agents could be compared and identified. Biochips may also be useful in hospitals for detecting specific causes of local infection and in agriculture for testing for pesticides in the soil.

A biochip called the **MAGIChip** is being developed jointly by the Argonne National Laboratory and the Russian Academy of Sciences' W. A. Engelhardt Institute of Molecular Biology. Commercial use of biochips is seen as about five years away.

bioinformatics

Bioinformatics is the science of developing computer **databases** and **algorithms** for the purpose of speeding up and enhancing biological research. Bioinformatics is being used most noticeably in the Human Genome Project, the effort to identify the 80,000 genes in human DNA. New academic programs are training students in bioinformatics by providing them with backgrounds in molecular biology and in computer science, including database design and analytical approaches. Rensselaer Polytechnic Institute in Troy, New York, is offering both a bachelor of science and a master's degree in bioinformatics and molecular biology.

Much information that has been captured is not yet available in the databases. The databases themselves are expected to be publicly online and Internet-accessible by the end of 2003. Database information will be analyzed for new information as new algorithms are developed. Motorola is working on a **biochip**, a processor expressly designed to speed up experiments with different combinations of protein-DNA reactions.

biomechatronics

Biomechatronics is the interdisciplinary study of biology, mechanics, and electronics. Biomechatronics focuses on the interactivity of biological organs (including the brain) with **electromechanical** devices and systems. Universities and research centers worldwide have taken notice of biomechatronics in light of its potential for development of advanced medical devices and life-support systems. Primitive biomechatronic devices have existed for some time; the heart pacemaker and the defibrillator are examples. More exciting biometchatronic possibilities that scientists foresee in the near future include pancreas pacemakers for diabetics, mentally controlled electronic muscle stimulators for stroke and accident survivors, cameras that can be wired into the brain allowing blind people to see, and microphones that can be wired into the brain allowing deaf people to hear.

biometrics

Biometrics is the science and technology of measuring and statistically analyzing biological data. In information technology, biometrics usually refers to technologies for measuring and analyzing human body characteristics such as fingerprints, eye retinas and irises, voice patterns, facial patterns, and hand measurements, especially for the **authentication** of someone. Often seen in science-fiction action adventure movies, face pattern matchers and body scanners seem about to emerge as replacements for computer passwords. A fingerprint reader is now sold by Compaq Computer. It plugs into a **parallel port** on back of the computer. Compaq believes that help desk centers will appreciate systems with fingerprint rather than password authentication since up to 50% of calls are from users having trouble with their passwords.

Fingerprint and other biometric devices consist of a reader or scanning device, software that converts the scanned information into digital form, and, wherever the data is to be analyzed, a **database** that stores the biometric data for comparison with entered biometric data. In converting the biometric input, the software identifies specific points of data as *match points*. The match points are processed using an **algorithm** into a value that can be compared with biometric data scanned when a user tries to gain access.

Besides fingerprints, voice patterns, face measurement, and retina and iris measurements are considered viable approaches. Miros makes a product called TrueFace that analyzes patterns using a **neural network** approach.

Fingerprint, facial, or other biometric data can be placed on a **smart card** and users can present both the smartcard and their fingerprints or faces to merchants, banks, or telephones for an extra degree of authentication. Some analysts feel that biometric data is likely to be used instead of a password to authorize sales and other transactions.

IBM, Microsoft, Novell, and others are developing a standard, called BioAPI, that will allow different manufacturers' software to interact. There are privacy concerns about the gathering and proliferation of biometric data. One suggestion is to **encrypt** the biometric data and discard the original data.

biomimetic

Biomimetic refers to human-made processes, substances, devices, or systems that imitate nature. The art and science of designing and building biomimetic apparatus is called biomimetics, and is of special interest to researchers in nanotechnology, robotics, artificial intelligence (AI), the medical industry, and the military.

Some biomimetic processes have been in use for years. An example is the artificial synthesis of certain vitamins and antibiotics. More recently, biomimetics have been suggested as applicable in the design of **machine vision** systems, machine hearing systems, signal amplifiers, navigational systems, and data converters. The neural network (which has suffered through on-again, off-again status in the opinions of prominent researchers) is a hypothetical biomimetic computer that works by making associations and educated guesses, and that can learn from its own mistakes.

Other possible applications of biomimetics include nanorobot antibodies that seek and destroy disease-causing bacteria, artificial organs, artificial arms, legs, hands, and feet, and various electronic devices. One of the more intriguing ideas is the so-called **biochip**, a microprocessor that grows from a starter crystal in much the same way that a seed grows into a tree, or a fertilized egg grows into an embryo.

Also see **nanotechnology** and **self-assembly**.

BIOS

BIOS is the program a personal computer's **microprocessor** uses to get the computer system started after you turn it on. It also manages data flow between the computer's **operating system** and attached devices such as the **hard disk, video adapter, keyboard, mouse, and printer**.

BIOS is an integral part of your computer and comes with it when you bring it home. (In contrast, the operating system can either be preinstalled by the manufacturer or vendor or installed by the user.) BIOS is a program that is made accessible to the microprocessor on an erasable programmable read-only memory (EPROM) chip. When

you turn on your computer, the microprocessor passes control to the BIOS program, which is always located at the same place on EPROM.

When BIOS boots up (starts up) your computer, it first determines whether all of the attachments are in place and operational and then it loads the operating system (or key parts of it) into your computer's random access memory (RAM) from your hard disk or diskette drive.

With BIOS, your operating system and its applications are freed from having to understand exact details (such as hardware addresses) about the attached input/output devices. When device details change, only the BIOS program needs to be changed. Sometimes this change can be made during your system setup. In any case, neither your operating system or any applications you use need to be changed.

Although BIOS is theoretically always the intermediary between the microprocessor and I/O device control information and data flow, in some cases, BIOS can arrange for data to flow directly to memory from devices (such as video cards) that require faster data flow to be effective.

bipolar 8-zero substitution

See "B8ZS"

bipolar signaling

See also **unipolar signaling**.

Bipolar signaling, also called *bipolar transmission*, is a **baseband** method of sending **binary** data over wire or cable. There are two logic states, low and high, represented by the digits 0 and 1 respectively.

The illustration shows a bipolar signal as it might appear on the screen of an oscilloscope. Each horizontal division represents one **bit** (binary digit). The logic 0 state is -3 volts and logic 1 is $+3$ volts. This is *positive logic*. Alternatively, logic 0 might be $+3$ volts, and logic 1 might be -3 volts; this would be *negative logic*. Whether positive or negative logic is used, the voltages representing the low and high states are equal and opposite; over time, the average voltage is approximately equal to 0.

A bipolar signal resembles an **alternating current** (AC) rectangular wave, except that the **frequency** is not constant. The **bandwidth** of the signal is inversely proportional to the duration of each data bit. Typical data speeds in baseband are several megabits per second (Mbps); hence the duration of each bit is a fraction of a microsecond.

bipolar transistor

See also field-effect transistor (FET) and **transistor**.

A bipolar transistor is a semiconductor device commonly used for amplification. The device can amplify **analog** or **digital** signals. It can also switch DC or function as an oscillator. Physically, a bipolar transistor amplifies **current**, but it can be connected in circuits designed to amplify voltage or power.

There are two major types of bipolar transistors, called *PNP* and *NPN*. A PNP transistor has a layer of N-type semiconductor between two layers of P-type material. An NPN transistor has a layer of P-type material between two layers of N-type material. In P-type material, electric charges are carried mainly in the form of **electron** deficiencies called *holes*. In N-type material, the charge carriers are primarily electrons.

The bipolar transistor has advantages and disadvantages relative to the **field-effect transistor** (field-effect transistor). Bipolar devices can switch signals at high speeds, and can be manufactured to handle large currents so that they can serve as high-power amplifiers in audio equipment and in **wireless** transmitters. Bipolar devices are not especially effective for weak-signal amplification, or for applications requiring high circuit **impedance**.

Bipolar transistors are fabricated onto silicon integrated circuit (IC) **chips**. A single IC can contain many thousands of bipolar transistors, along with other components such as resistors, capacitors, and diodes.

bipolar transmission

See "bipolar signaling"

birdie

A birdie is a false, or phantom, signal that appears in a superheterodyne **wireless** receiver. Birdies are internally generated, resulting from the outputs of the oscillators that form part of the receiver circuit. They usually sound like

unmodulated carriers—signals with “dead air.” Occasionally they are modulated by clicks, humming sounds, or audible tones.

Birdies can occur as a result of the receiver being tuned to a **frequency** that is a multiple of the output frequency of one of the internal oscillators. These signals are known as harmonics. A birdie might also be heard at a frequency corresponding to the sum or the difference of the internal **oscillator** frequencies. These signals are called mixing products. Birdies are inevitable in any superheterodyne wireless receiver. However, in a well-engineered receiver, most or all of the birdies occur at frequencies outside the normal range of operation, so they have little or no detrimental effect on receiver performance.

A birdie is not the same thing as a spurious response. If a receiver picks up a signal whose transmitter is operating at a frequency other than that to which the receiver is tuned, the **modulation** of the unwanted signal will be heard or decoded. In some cases, two or more strong external signals can combine in a receiver’s radio-frequency amplifier, causing numerous spurious responses. This phenomenon, called intermodulation (“intermod”), can be a problem in downtown metropolitan areas where many wireless transmitters operate simultaneously.

bis

The word (also used as a prefix or suffix) *bis*, applied to some **modem protocol** standards, is Old Latin for “repeat” (akin to Old High German “twice”). When a protocol ends with “bis,” it means that it’s the second version of that protocol.

Similarly, *ter* is from Old Latin meaning “three times.” The suffix *terbo* in the V.xx modem protocol is an invented word based on the Old Latin *ter* and the word *turbo* (Latin for “whirling top” or “whirlwind”) meaning “speed.” V.32terbo is the third version developed of the V.32 modem protocol.

BISDN

See “Broadband Integrated Services Digital Network”

bit

A bit (short for *binary digit*) is the smallest unit of **data** in a computer. A bit has a single **binary** value, either 0 or 1. Although computers usually provide **instructions** that can test and manipulate bits, they generally are designed to store data and execute instructions in bit multiples called bytes. In most computer systems, there are eight bits in a **byte**. The value of a bit is usually stored as either above or below a designated level of electrical charge in a single capacitor within a memory device.

Half a byte (four bits) is called a **nibble**. In some systems, the term **octet** is used for an eight-bit unit instead of byte. In many systems, four eight-bit bytes or octets form a 32-bit

word. In such systems, instruction lengths are sometimes expressed as full-word (32 bits in length) or half-word (16 bits in length).

In telecommunication, the **bit rate** is the number of bits that are transmitted in a given time period, usually a second.

bit bucket

Computer jargon users say that data which has been lost or thrown away has gone in the bit bucket. (A **bit**, short for *binary digit*, is the smallest unit of **data** in a computer.)

For example, once you read an e-mail note and then delete it, it goes into the bit bucket (which sometimes is represented by a trash can icon). Of course, you can always look at deleted data as being recycled to make way for more new data.

In data that is truncated, the data after the truncation point gets put in the bit bucket. Actually, it doesn’t get put anywhere; it just isn’t considered at all by the program that does the truncation.

bit depth

In **digital audio**, bit depth describes the potential accuracy of a particular piece of hardware or software that processes audio data. In general, the more bits that are available, the more accurate the resulting output from the data being processed.

Bit depth is frequently encountered in specifications for analog-to-digital converters (**ADCs**) and digital-to-analog converters (**DACs**), when reading about software **plug-ins**, and when recording audio using a professional medium such as a **digital audio workstation** or a **Digital Audio Tape** machine.

Bit depth is the number of **bits** you have in which to describe something. Each additional bit in a binary number doubles the number of possibilities. By the time you have a 16-bit sequence, there are 65,536 possible levels. Add one more bit, and you double the possible accuracy (to 131,072 levels). When you have a 24-bit process or piece of 24-bit hardware, there are 16,777,216 available levels of audio.

bit error rate

In telecommunication transmission, the bit error rate (BER) is the percentage of bits that have errors relative to the total number of bits received in a transmission, usually expressed as ten to a negative power. For example, a transmission might have a BER of 10 to the minus 6, meaning that, out of 1,000,000 bits transmitted, one bit was in error. The BER is an indication of how often a **packet** or other data unit has to be retransmitted because of an error. Too high a BER may indicate that a slower data rate would actually improve overall transmission time for a given amount of transmitted data since the BER might be reduced, lowering the number of packets that had to be resent.

V,W

X,Y,Z

A BERT (bit error rate test or tester) is a procedure or device that measures the BER for a given transmission.

bit map

A bit map (often spelled "bitmap") defines a display space and the color for each **pixel** or "bit" in the display space. A **Graphics Interchange Format** and a **JPEG** are examples of graphic image file types that contain bit maps.

A bit map does not need to contain a bit of color-coded information for each pixel on every row. It only needs to contain information indicating a new color as the display scans along a row. Thus, an image with much solid color will tend to require a small bit map.

Because a bit map uses a fixed or **raster graphics** method of specifying an image, the image cannot be immediately rescaled by a user without losing definition. A **vector graphics** graphic image, however, is designed to be quickly rescaled. Typically, an image is created using vector graphics and then, when the artist is satisfied with the image, it is converted to (or saved as) a raster graphic file or bit map.

bit rate

In **digital** telecommunication, the bit rate is the number of **bits** that pass a given point in a telecommunication network in a given amount of time, usually a second. Thus, a bit rate is usually measured in some multiple of bits per second—for example, kilobits, or thousands of bits per second (**Kbps**). The term *bit rate* is a synonym for **data transfer rate** (or simply *data rate*). *Bit rate* seems to be used more often when discussing transmission technology details and *data transfer rate* (or *data rate*) when comparing transmission technologies for the end user.

bit robbing

Bit robbing is a technique used in **signaling** on the **T-carrier system**, the widely-used system for transmitting both voice and data in **digital** form in the public switched telephone network (**PSTN**) and in private networks. In the basic T-1 system, a 193 bit frame, serving 24 **channels**, is transmitted in a sequence of 12 frames that are referred to as a *superframe*. Special signaling information, such as whether a voice channel is on-hook or off-hook, is included within the superframe by using a bit (called the *a bit*) that is "robbed" from the sixth frame as a signaling bit and another bit (the *b bit*) that is robbed from the 12th frame.

Bit robbing is acceptable for voice conversations or data transmissions that are received by a modem but not for "pure" data transmission (where every bit is significant). Bit robbing is the reason that a 64 **Kbps** channel only carries 56 Kbps of usable data. Bit robbing is a form of in-band signaling.

bit stream

A bit stream is a contiguous sequence of **bits**, representing a stream of **data**, transmitted continuously over a communications path, serially (one at a time).

bit stuffing

In telecommunication, bit stuffing is the addition of a small number of **binary** digits to a transmission unit in order to fill it up to a standard size or to help synchronize signaling rates between points in a network. The receiver knows how to detect and remove or disregard the stuffed bits.

For example, the timing or bit rate of **T-carrier system** signals is constantly synchronized between any terminal device and an adjacent **repeater** or between any two repeaters. The synchronization is achieved by detecting the transition in polarity for 1 bits in the data stream. (T-1 signaling uses *bipolar* signaling, where each successive bit with a value of 1 is represented by **voltage** with a reverse polarity from the previous bit. Bits with a value of 0 are represented by a no-voltage time slot.) If more than 15 bits in a row are sent with a 0 value, this "lull" in 1 bits that the system depends on for synchronization may be long enough for two end points to become out of synchronization. To handle this situation (the sequence of more than 15 0 bits), the signal is "stuffed" with a short, unique bit pattern (which includes some 1 bits) that is recognized as a synchronization pattern. The receiving end removes the stuffed bits and restores the bit stream to its original sequence.

bitmap

See "bit map"

BITNET

BITNET is a network of academic sites comparable to but separate from the Internet. BITNET originated the utility known as the **list server** and Internet users can get access to BITNET list servers (or subscription lists). E-mail can be exchanged between users on BITNET and the Internet. As the Internet grows, BITNET is becoming less important.

bits per second

In data communications, bits per second (abbreviated bps) is a common measure of data speed for computer **modem** and transmission carriers. As the term implies, the speed in bps is equal to the number of bits transmitted or received each second. The duration *d* of a data bit, in seconds, is inversely proportional to the **digital** transmission speed *s* in bps:

$$d = 1/s$$

Larger units are sometimes used to denote high data speeds. One kilobit per second (abbreviated Kbps in the U.S.; kbps elsewhere) is equal to 1,000 bps. One megabit per second (Mbps) is equal to 1,000,000 bps or 1,000 Kbps.

Computer modems for **twisted pair** telephone lines usually operate at speeds between 14.4 and 57.6 Kbps. The most common speeds are 28.8 and 33.6 Kbps. So-called “cable modems,” designed for use with TV cable networks, can operate at more than 100 Kbps. Fiberoptic modems are the fastest of all; they can send and receive data at many Mbps.

The **bandwidth** of a signal depends on the speed in bps. With some exceptions, the higher the bps number, the greater is the nominal signal bandwidth. (Speed and bandwidth are, however, not the same thing.) Bandwidth is measured in standard frequency units of **kHz** or **MHz**.

Data speed was formerly specified in terms of **baud**, which is a measure of the number of times a digital signal changes state in one second. Baud, sometimes called the “baud rate,” is almost always a lower figure than bps for a given digital signal. The terms are often used interchangeably, even though they do not refer to the same thing. If you hear that a computer modem can function at “33,600 baud” or “33.6 kilobaud,” you can be reasonably sure that the term is being misused, and the figures actually indicate bps.

BizTalk

BizTalk is an industry initiative headed by Microsoft to promote Extensible Markup Language (**XML**) as the common data exchange language for e-commerce and application integration on the Internet. While not a standards body per se, the group is fostering a common XML message-passing architecture to tie systems together. BizTalk says that the growth of e-commerce requires businesses using different computer technologies to have a means to share data. Accepting XML as a platform-neutral way to represent data transmitted between computers, the BizTalk group provides guidelines, referred to as the BizTalk Framework, for how to publish **schema** (standard data structures) in XML and how to use XML messages to integrate software programs.

In addition to Microsoft, other vendors such as **SAP** and CommerceOne are supporting BizTalk. Microsoft offers BizTalk Server 2000, which can implement XML-based data integration. The server software includes tools to create and design XML definitions, map data from one definition to another, and manage process flow, document verification, and data exchange and processing.

black hat

Black hat is used to describe a **hacker** (or, if you prefer, **cracker**) who breaks into a computer system or network with malicious intent. Unlike a **white hat** hacker, the black hat hacker takes advantage of the break-in, perhaps destroying files or stealing data for some future purpose. The black hat hacker may also make the exploit known to other hackers and/or the public without notifying the victim. This gives others the opportunity to exploit the vulnerability before the organization is able to secure it.

The term comes from old Western movies, where heroes often wore white hats and the “bad guys” wore black hats.

Blackberry

BlackBerry is a **handheld** device made by RIM (Research In Motion) that competes with another popular handheld, the **Palm**, and is marketed primarily for its **wireless e-mail** handling capability. Through partners, BlackBerry also provides access to other Internet services. Like the Palm, BlackBerry is also a personal digital assistant (**PDA**) that can include software for maintaining a built-in address book and personal schedule. In addition, it can also be configured for use as a **pager**.

Exploiting the trends toward worker mobility and the growth in e-mail traffic, BlackBerry’s makers provide software that forwards a user’s incoming mail from the user’s individual e-mail account or to a user’s corporate e-mail address through a customer-selected wireless network to the BlackBerry where it is stored for reading. Outgoing e-mail goes directly to the addressee from the BlackBerry but a copy of the e-mail also goes to the user’s home e-mail box. Software is also provided for synchronizing address books and schedules with the desktop system.

Compared to the Palm, the BlackBerry is somewhat simpler and offers fewer options and applications. Its unnamed **operating system** apparently takes up a relatively small space on its 4 megabyte flash memory, which is also used to store user data. Unlike the Palm, whose users write text using a stylus, BlackBerry offers a tiny keyboard that some users say is faster to use in spite of its size. BlackBerry comes in two configurations, one with a slightly larger **LCD** display.

blind carbon copy

See “Bcc”

BLOB

1) In computers, a **BLOB** (binary large object), pronounced BLAHB and sometimes spelled in all lower case, is a large **file**, typically an **image** or sound file, that must be handled (for example, uploaded, downloaded, or stored in a **database**) in a special way because of its size. According to Eric Raymond, the main idea about a BLOB is that the handler of the file (for example, the database manager) has no way of understanding the file in order to figure out how to deal with it—it might as well be a large piece of coal, but there it is and now what? Other sources emphasize that the term was coined to refer to big data objects and to connote the problems they sometimes present in handling them. One application that deals with BLOBs is the database storage of large multimedia objects, such as films and television programs.

2) In computer graphics, a blob (lowercase) is a visual object that, according to one user of the Persistence of Vision ray tracer, a freeware image creation tool, has "an interesting shape type" that is flexible and amenable to animation.

3) In general, a blob is an amorphous and undefinable object. There are blobs in astronomy as well as in unidentified flying object studies. There was a science-fiction movie called "The Blob."

block cipher

A block **cipher** is a method of **encrypting text** (to produce **ciphertext**) in which a cryptographic key and **algorithm** are applied to a block of data (for example, 64 contiguous **bits**) at once as a group rather than to one bit at a time. The main alternative method, used much less frequently, is called the **stream cipher**.

So that identical blocks of text do not get encrypted the same way in a message (which might make it easier to decipher the ciphertext), it is common to apply the ciphertext from the previous encrypted block to the next block in a sequence. So that identical messages encrypted on the same day do not produce identical ciphertext, an *initialization vector* derived from a *random number generator* is combined with the text in the first block and the key. This ensures that all subsequent blocks result in ciphertext that doesn't match that of the first encrypting.

blog

On a Web site, a blog, a short form of *Web log* or *weblog*, is a personal journal that is frequently updated and intended for general public consumption. Blogs generally represent the personality of the author or the Web site and its purpose. Topics sometimes include brief philosophical musings, commentary on Internet and other social issues, and links to other sites the author favors. The essential characteristics of the blog are its journal form, typically a new entry each day, and its informal style.

The author of a blog is often referred to as a blogger. People who post new journal entries to their blog may often say they blogged today, they blogged it to their site, or that they still have to blog.

blogging

See "blog"

Blowfish

Blowfish is an **encryption algorithm** that can be used as a replacement for the **DES** or **IDEA** algorithms. It is a symmetric (that is, a secret or **private key**) **block cipher** that uses a variable-length **key**, from 32 bits to 448 bits, making it useful for both domestic and exportable use. (The U.S. government forbids the exportation of encryption software using keys larger than 40 bits except in special cases.)

Blowfish was designed in 1993 by Bruce Schneier as an alternative to existing encryption algorithms. Designed with 32-bit instruction processors in mind, it is significantly faster than DES. Since its origin, it has been analyzed considerably. Blowfish is unpatented, license-free, and available free for all uses.

blue bomb

A "blue bomb" (also known as "WinNuke") is a technique for causing the Windows **operating system** of someone you're communicating with to crash or suddenly terminate. The "blue bomb" is actually an out-of-band network **packet** containing information that the operating system can't process. This condition causes the operating system to "crash" or terminate prematurely. The operating system can usually be restarted without any permanent damage other than possible loss of unsaved data when you crashed.

The blue bomb derives its name from the effect it sometimes causes on the display as the operating system is terminating—a white-on-blue error screen that is commonly known as **blue screen of death**. Blue bombs are sometimes sent by multi-player game participants who are about to lose or users of Internet Relay Chat (**IRC**) who are making a final comment. This is known as "nuking" someone. A commonly-used program for causing the blue bomb is WinNuke. Many Internet service providers are filtering out the packets so they don't reach users.

Blue Book

The Blue Book is the informal name for the standard specification document for *stamped multisection* (also known as the **enhanced CD** or **E-CD**) disk format, developed in 1995 from a supplement to Philips and Sony's 1988 **Orange Book**. The Blue Book defines a format for enhanced CDs for inclusion of multimedia data (such as video clips, text, and images) on a standard audio **CD**. The disks play normally on a CD-player, and display the extra data when they are played on a device with multimedia capabilities, such as a computer's **CD-ROM** drive, or a **CD-i** player.

Like all CD formats, the Blue Book specifications are built on the details of the **Red Book**, which defined the format for audio CDs. The Blue Book specifies two sessions: up to 99 Red Book audio tracks in the first session (closest to the center of the disk), and a **Yellow Book**-based data track in the second session (closest to the outside edge of the disk). Other Blue Book details include the Red Book disk specification, file formats (including CD Plus information files), and an **ISO 9660**-compatible directory structure to organize the various types of data. The Blue Book is supported as a licensed standard definition by Philips, Sony, Microsoft, and Apple.

blue laser

A blue laser is a **laser** (pronounced LAY-zer) with a shorter **wavelength** than the red laser used in today's **compact disk** and **laser printer** technologies and the ability to store and read two to four times the amount of data. When available in the marketplace, personal computer users may be able to buy a laser printer with a resolution up to 2400 pixels or dots per inch at an affordable price. The same technology in compact disk and CD-ROM devices may provide a dramatic breakthrough in storage capability without an increase in device size.

A laser (an acronym for "light amplification by stimulated emission of radiation") is a *coherent* (meaning all one wavelength, unlike ordinary light which showers on us in many wavelengths) and focused beam of *photons* or particles of light. The photons are produced as the result of a chemical reaction between special materials and then focused into a concentrated beam in a tube containing reflective mirrors. In the blue laser technology, the special material is **gallium nitride**. Even a small shortening of wavelength of light can have a dramatic effect in the ability to store and access data. A shorter wavelength allows a single item of data (0 or 1) to be stored in a smaller space.

Red lasers used in today's technologies have wavelengths of over 630 nanometers (or 630 billionths of a meter). The blue laser has a wavelength of 414 nanometers.

Shuji Nakamura, a Japanese researcher working in a small chemical company, Nichia Chemical Industries, built the first blue laser diode. However, Fujitsu and Xerox have also announced progress in the ability to manufacture blue laser diodes. Several companies, including Sony, have developed a blue-green laser. However, the shorter wavelength of the blue laser is much more of a breakthrough.

Cree Research and Hewlett-Packard are other companies making advances in this technology, some of which has been underwritten by the U.S. Defense Advanced Research Projects Agency (DARPA).

blue screen of death

The blue screen of death is a rather terrifying display image containing white text on a blue background that is generated by Windows operating systems when the system has suddenly terminated with an error. The system is locked up and must be restarted. The blue screen may include some **hexadecimal** values from a **core dump** that may help determine what caused the crash.

The blue screen of death can strike anywhere. At the Comdex trade show, Microsoft Chairman Bill Gates encountered the blue screen during a demonstration of Windows 98. (He had a spare computer standing by.)

Bluetooth

Bluetooth is a computing and telecommunications industry specification that describes how mobile phones, computers, and personal digital assistants (PDAs) can easily interconnect with each other and with home and business phones and computers using a short-range **wireless** connection. Using this technology, users of cellular phones, pagers, and personal digital assistants such as the PalmPilot will be able to buy a three-in-one phone that can double as a portable phone at home or in the office, get quickly synchronized with information in a desktop or notebook computer, initiate the sending or receiving of a fax, initiate a print-out, and, in general, have all mobile and fixed computer devices be totally coordinated. The technology requires that a low-cost transceiver chip be included in each device. Products with Bluetooth technology are expected to appear in large numbers beginning in 2001.

How It Works

Each device is equipped with a microchip transceiver that transmits and receives in a previously unused frequency band of 2.45 GHz that is available globally (with some variation of bandwidth in different countries). In addition to data, up to three voice channels are available. Each device has a unique 48-bit address from the IEEE 802 standard. Connections can be point-to-point or multipoint. The maximum range is 10 meters. Data can be exchanged at a rate of 1 **megabit** per second (up to 2 Mbps in the second generation of the technology). A frequency hop scheme allows devices to communicate even in areas with a great deal of electromagnetic interference. Built-in encryption and verification is provided.

BMAN

BMAN (Broadband Metropolitan Area Network) is a telecommunications service from Sprint in the U.S. that provides corporate users in a metropolitan area with **broadband** access to the Internet on **optical fiber** lines in a system that preserves a connection even when one line is cut or fails. Using existing and supplemented infrastructure, BMAN uses a series of interlocking **rings** so that a connection can be restored within 60 milliseconds if a single line goes down. The system uses **Synchronous Optical Network multiplexing**. BMAN is the metropolitan part of Sprint's overall national network, which it calls ION (Integrated On-Demand Network).

BNC

A BNC (Bayonet Neil-Concelman, or sometimes British Naval Connector) connector is used to connect a computer to a **coaxial cable** in a **10BASE-2 Ethernet** network. 10BASE-2 is a 10 MHz **baseband** network on a cable extending up to 185 meters—the 2 is a rounding up to 200 meters—without a repeater cable. 10BASE-2 Ethernets are also known as

"**Thinnet**," "thin Ethernet," or "cheapernets." The wiring in this type of Ethernet is thin, 50 ohm, baseband coaxial cable. The BNC connector in particular is generally easier to install and less expensive than other coaxial connectors.

A BNC male connector has a pin that connects to the primary conducting wire and then is locked in place with an outer ring that turns into locked position.

Different sources offer different meanings for the letters BNC. However, our most knowledgeable source indicates that the B stands for a bayonet-type connection (as in the way a bayonet attaches to a rifle) and the NC for the inventors of the connector, Neil and Concelman.

BO2K

See "Back Orifice"

board

In computers, a board, depending on usage, can be short for **motherboard**, the physical arrangement of a computer's basic components and circuitry, or it can refer to an expansion board (or *card* or *adapter*), which fits into one of the computer's expansion **slots** and provides expanded capability.

BOC

BOC (Bell operating company) is a term for any of the 22 original companies (or their successors) that were created when AT&T was broken up in 1983 and given the right to provide local telephone service in a given geographic area. The companies had previously existed as subsidiaries of AT&T and were called the "Bell System." The purpose of the breakup was to create competition at both the local and long-distance service levels. BOCs compete with other, independent companies to sell local phone service. In certain areas, long-distance companies, including AT&T, can now compete for local service. Collectively, companies offering local phone service are referred to legally as local exchange carriers (**local exchange carrier**).

BOCs are not allowed to manufacture equipment and were initially not allowed to provide long-distance service. The **Telecommunications Act of 1996** now permits them to engage in long-distance business under certain circumstances. As of 1996, the BOCs consisted of original and successor companies to:

Bell Telephone Company of Nevada, Illinois Bell, Indiana Bell, Michigan Bell, New England Telephone and Telegraph Company, New Jersey Bell, New York Telephone Company, U S West Communications Company, South Central Bell, Southern Bell, Southwestern Bell, Bell Telephone of Pennsylvania, The Chesapeake and Potomac Telephone Company, The Chesapeake and Potomac Telephone Company of Maryland, The Chesapeake and Potomac Telephone

Company of Virginia, The Diamond State Telephone Company, The Ohio Bell Telephone Company, The Pacific Telephone and Telegraph Company, and the Wisconsin Telephone Company.

bogie

The term bogie, also spelled bogey, refers to a false blip on a radar display. The term is also used to describe radar echoes that occur for unknown reasons, especially in the military, where such a signal might indicate hostile aircraft. There are two types of bogies: those that occur because of some real but unidentified or irrelevant object (called "real bogies" for the purpose of this discussion), and those that occur as a result of no concrete external object ("imaginary bogies").

A "real bogie" can be caused by an aircraft, a missile, a flock of birds, a tall ground-based metal structure, a balloon with a large payload or a radar-reflective coating, or (perhaps) an extraterrestrial spacecraft. Thunderstorms produce radar echoes, as do concentrated weather phenomena such as tornadoes. Meteors passing through the atmosphere create trails of ionized gas that can return radar signals. In the military, "real bogies" are sometimes produced by dropping myriad scraps of metal foil from high-flying aircraft, producing diffuse echoes that blind enemy radar over large regions.

An "imaginary bogie" can occur because of an external signal having a frequency and pulse rate near, or identical to, that of the radar's internal transmitter. When the radar receiver picks up the offending signal, it cannot differentiate between that signal and a true echo, so a blip appears on the display. This is how radar jamming works. The blip might exhibit fantastic velocity or acceleration as viewed on the radar display.

In computerized radar, bogie signals might conceivably arise from a specialized **virus** or **Trojan horse**, or from the activities of a brilliant but malicious hacker. This is an example of how, as systems get increasingly sophisticated, they often become more vulnerable to electronic attack.

bogomips

Bogomips is a measurement provided in the **Linux operating system** that indicates in a relative way how fast the computer **processor** runs. The program that provides the measurement is called BogoMips. Written by Linus Torvalds, the main developer of **Linux**, BogoMips can indicate when you **boot** a computer whether the system options have been specified for optimum performance. You compare the bogomips for your computer with what they ought to be for your computer's particular type of processor. Torvalds named the program BogoMips (for "bogus (or fake) MIPS") to suggest that performance measurements between two computers can be misleading because not all contributing factors are stated or even understood. Although **MIPS** (millions of instructions per second) has been

frequently used in computer benchmarks, it's agreed that the variation of context tends to make the measurement misleading. Bogomips measures how many times the processor goes through a particular programming **loop** in a second.

BogoMIPS is built into some versions of Linux. It also exists as a stand-alone application program that you can download from certain Web sites. Currently, the record of 2182.35 bogomips was measured on a computer with an **AMD Athlon** microprocessor operating at 1,100 MHz.

boilerplate

In information technology, a boilerplate is a unit of writing that can be reused over and over without change. By extension, the idea is sometimes applied to reusable programming as in "boilerplate code." The term derives from steel manufacturing, where boilerplate is steel rolled into large plates for use in steam boilers. The implication is either that boilerplate writing has been time-tested and strong as "steel," or possibly that it has been rolled out into something strong enough for repeated reuse. Legal agreements, including software and hardware terms and conditions, make abundant use of boilerplates. The term is also used as an adjective as in "a boilerplate paragraph" and also as in "The entire document was boilerplate."

A boilerplate can be compared to a certain kind of **template**, which can be thought of as a fill-in-the-blanks boilerplate. Some typical boilerplates include: mission statements, safety warnings, commonly used installation procedures, copyright statements, and responsibility disclaimers.

In the 1890s, boilerplate was actually cast or stamped in metal ready for the printing press and distributed to newspapers around the United States. Until the 1950s, thousands of newspapers received and used this kind of boilerplate from the nation's largest supplier, the Western Newspaper Union. Some companies also sent out press releases as boilerplate so that they had to be printed as written.

bolt-on

On the Internet, bolt-on, perhaps inspired by **add-on**, is used to describe products and systems that can be quickly but securely attached to an existing **Web site**. The term most often describes some **e-commerce** solution for adding an online store to a Web site. A "bolt-on e-commerce solution" typically allows a Web site owner to create customized Web catalog pages, using a furnished template that includes a shopping cart approach for multiple item orders, and to have these pages hosted at the solution provider's server, where orders can be taken and reported to the Web site. Solution packages typically include the handling of credit-card applications and credit checking.

bookmark

Using a World Wide Web **browser**, a bookmark is a saved link to a Web **page** that has been added to a list of saved links. When you are looking at a particular Web site or **home page** and want to be able to quickly get back to it later, you can create a bookmark for it. You can think of your browser as a book full of (millions of) Web pages and a few well-placed bookmarks that you have chosen. The list that contains your bookmarks is the "bookmark list" (and sometimes it's called a "hotlist.")

Netscape and some other browsers use the bookmark idea. Microsoft's Internet Explorer uses the term "favorite."

bookmark portal

A bookmark portal is a free application service provider (**ASP**) Web site that allows registered users to save "bookmark" (Netscape) or "favorite" (Internet Explorer) Web links so that they can be accessed at any time from any Internet-connected device. With a bookmark portal, it is not necessary to transfer bookmarks from browser to browser or from machine to machine; instead, the user simply logs on to the ASP's Web site to access their bookmarks.

Many bookmark sites give users the option of creating a "personal web portal" where it is possible to manage multiple e-mail accounts and calendars, share files as well as bookmarks, and synchronize personal digital assistant (**PDA**) devices remotely.

Boole, George

See "George Boole"

Boolean

The term "Boolean," often encountered when doing searches on the Web (and sometimes spelled "boolean"), refers to a system of logical thought developed by the English mathematician and computer pioneer, George Boole (1815-64). In Boolean searching, an "and" operator between two words or other values (for example, "pear AND apple") means one is searching for documents containing both of the words or values, not just one of them. An "or" operator between two words or other values (for example, "pear OR apple") means one is searching for documents containing either of the words.

In computer operation with binary values, Boolean logic can be used to describe electromagnetically charged memory locations or circuit states that are either charged (1 or true) or not charged (0 or false). The computer can use an AND gate or an OR gate operation to obtain a result that can be used for further processing. The following table shows the results from applying AND and OR operations to two compared states:

#

0 AND 0 = 0 1 AND 0 = 0 1 AND 1 = 1
 0 OR 0 = 0 0 OR 1 = 1 1 OR 1 = 1

A

For a summary of logic operations in computers, see **logic gate**.

B

boot

Tip: Make sure you have a **bootable floppy** diskette so you can restore your hard disk in the event it gets infected with a boot **virus**.

To boot (as a verb; also "to boot up") a computer is to load an **operating system** into the computer's main memory or random access memory (**RAM**). Once the operating system is loaded (and, for example, on a PC, you see the initial Windows or Mac desktop screen), it's ready for users to run **applications**. Sometimes you'll see an instruction to "reboot" the operating system. This simply means to reload the operating system (the most familiar way to do this on PCs is pressing the Ctrl, Alt, and Delete keys at the same time).

On larger computers (including **mainframe**), the equivalent term for "boot" is "Initial Program Load" (**IPL**) and for "reboot" is "re-IPL." Boot is also used as a noun for the act of booting, as in "a system boot." The term apparently derives from "bootstrap" which is a small strap or loop at the back of a leather boot that enables you to pull the entire boot on. There is also an expression, "pulling yourself up by your own bootstraps," meaning to leverage yourself to success from a small beginning. The booting of an operating system works by loading a very small program into the computer and then giving that program control so that it in turn loads the entire operating system.

Booting or loading an operating system is different from installing it, which is generally an initial one-time activity. (Those who buy a computer with an operating system already installed don't have to worry about that.) When you install the operating system, you may be asked to identify certain options or configuration choices. At the end of installation, your operating system is on your hard disk ready to be booted (loaded) into random access memory, the computer storage that is closer to the microprocessor and faster to work with than the hard disk. Typically, when an operating system is installed, it is set up so that when you turn the computer on, the system is automatically booted as well. If you run out of storage (memory) or the operating system or an application program encounters an error, you may get an error message or your screen may "freeze" (you can't do anything). In these events, you may have to reboot the operating system.

How Booting Works

Note: This procedure may differ slightly for Mac, UNIX, OS/2, or other operating systems.

When you turn on your computer, chances are that the operating system has been set up to boot (load into RAM) automatically in this sequence:

1. As soon as the computer is turned on, the Basic Input-Output System (**BIOS**) on your system's read-only memory (**ROM**) chip is "woken up" and takes charge. BIOS is already loaded because it's built-in to the ROM chip and, unlike random access memory (**RAM**), ROM contents don't get erased when the computer is turned off.
2. BIOS first does a "power-on self test" (POST) to make sure all the computer's components are operational. Then the BIOS's boot program looks for the special boot programs that will actually load the operating system onto the hard disk.
3. First, it looks on drive A (unless you've set it up some other way or there is no diskette drive) at a specific place where operating system boot files are located. (If the operating system is MS-DOS, for example, it will find two files named IO.SYS and MSDOS.SYS.) If there is a diskette in drive A but it's not a system disk, BIOS will send you a message that drive A doesn't contain a system disk. If there is no diskette in drive A (which is the most common case), BIOS looks for the system files at a specific place on your hard drive.
4. Having identified the drive where boot files are located, BIOS next looks at the first *sector* (a 512-byte area) and copies information from it into specific locations in RAM. This information is known as the *boot record* or **Master Boot Record**.
5. It then loads the boot record into a specific place (**hexadecimal** address 7C00) in RAM.
6. The boot record contains a program that BIOS now branches to, giving the boot record control of the computer.
7. The boot record loads the initial system file (for example, for DOS systems, IO.SYS) into RAM from the diskette or hard disk.
8. The initial file (for example, IO.SYS, which includes a program called SYSINIT) then loads the rest of the operating system into RAM. (At this point, the boot record is no longer needed and can be overlaid by other data.)
9. The initial file (for example, SYSINIT) loads a system file (for example, MSDOS.SYS) that knows how to work with the BIOS.
10. One of the first operating system files that is loaded is a system configuration file (for DOS, it's called CONFIG.SYS). Information in the configuration file tells the loading program which specific operating system files need to be loaded (for example, specific device **driver**).

V,W

X,Y,Z

11. Another special file that is loaded is one that tells which specific applications or commands the user wants to have included or performed as part of the boot process. In DOS, this file is named AUTOEXEC.BAT. In Windows, it's called WIN.INI.
12. After all operating system files have been loaded, the operating system is given control of the computer and performs requested initial commands and then waits for the first interactive user input.

bootable floppy

A bootable floppy is a diskette containing a back-up copy of your **hard disk** master boot record (MBR). In the event that the master boot record becomes "infected" by a **boot virus**, having a bootable floppy will allow you to load it back onto your hard disk. (Otherwise, you may have to reformat your hard disk which first erases everything on the disk including files you may not have a backup copy of. Even if you do, reformatting your hard disk will mean you have to reinstall everything you've backed up, a time-consuming procedure at the very least.)

BOOTP

BOOTP (Bootstrap Protocol) is a **protocol** that lets a network user be automatically configured (receive an **IP address**) and have an **operating system boot** or initiated without user involvement. The BOOTP **server**, managed by a network administrator, automatically assigns the IP address from a pool of addresses for a certain duration of time.

BOOTP is the basis for a more advanced network manager protocol, the Dynamic Host Configuration Protocol (DHCP).

Bootstrap Protocol

See "BOOTP"

bootstrapping

Bootstrapping is the leveraging of a small initial effort into something larger and more significant. A bootstrap is a small strap or loop at the back of a leather boot that enables you to pull the entire boot on. There is also a common expression, "pulling yourself up by your own bootstraps," meaning to leverage yourself to success from a small beginning.

The term **boot** is derived from *bootstrapping*. The booting of an **operating system** works by loading a very small program into the computer and then giving that program control so that it in turn loads the entire operating system.

Border Gateway Protocol

See "BGP"

bot

A bot (short for "robot") is a program that operates as an **agent** for a user or another program or simulates a human activity. On the Internet, the most ubiquitous bots are the programs, also called **spiders** or **crawlers**, that access Web sites and gather their content for **search engine** indexes.

A **chatbot** is a program that can simulate talk with a human being. One of the first and most famous chatbots (prior to the Web) was Eliza, a program that pretended to be a psychotherapist and answered questions with other questions.

Red and Andrette are two examples of programs that can be customized to answer questions from users seeking service for a product. Such a program is sometimes called a *virtual representative* or a *virtual service agent*.

Shoptbots are programs that shop around the Web on your behalf and locate the best price for a product you're looking for. There are also bots such as OpenSesame that observe a user's patterns in navigating a Web site and customize the site for that user.

Knowbots are programs that collect knowledge for their users by automatically visiting Internet sites and gathering information that meets certain specified criteria.

bottleneck

A bottleneck is a stage in a process that causes the entire process to slow down or stop. For instance, if your dial-up Internet service provider (ISP) promises you Internet access at 56 **Kbps**, but your **modem** can only handle 14.4 Kbps, your modem's slow performance would be a bottleneck. The term bottleneck is derived from the narrow part of a bottle used to slow down the flow of liquid so that it doesn't flow too fast. However, in information technology, the bottleneck metaphor describes a link in a process that tends to slow down the entire process.

In "The Goal," a best-selling book about business development, author Eliyahu M. Goldratt's fictional character, factory manager Alex Rogo, struggles with bottlenecks in manufacturing and distribution in what Goldratt calls the "theory of constraints." Business Week credits Goldratt with inspiring businesses across America to look closely at how bottlenecks affect their ability to make money. A distribution center that receives goods faster than they can ship them out, for example, is forced to stockpile goods (often inefficiently) and becomes a bottleneck. Goldratt urges managers to step back and examine where the bottlenecks occur, determine why they are occurring, and find the most **elegant solution** to resolve them—which may or may not involve technology.

bounce e-mail

Bounce e-mail (sometimes referred to as *bounce mail*) is electronic mail that is returned to the sender because it cannot be delivered for some reason. Unless otherwise arranged, bounce e-mail usually appears as a new note in your inbox. E-mail users can encounter bounce e-mail because an addressee has changed his or her address, because their mail box is full, because the note is misaddressed, or for some other reason.

Bounce e-mail can be handled by a program when sending e-mail to a distribution list and most e-mail distribution list vendors include this capability. Such a bounce handler can retry later, unsubscribe the addressee from the list, or take some other action.

Some products and individuals have developed bounce e-mail handlers that recognize **spam** messages and return a bounce message so that the recipient will be taken off the list.

Some products and users use the term *bounce* to mean "forward a received note to someone else."

bouncing

See "debouncing"

Bourne shell

The Bourne shell is the original **UNIX shell** (command execution program, often called a *command interpreter*) that was developed at AT&T. Named for its developer, Stephen Bourne, the Bourne shell is also known by its program name, *sh*. The shell prompt (character displayed to indicate readiness for input) used is the \$ symbol. The Bourne shell family includes the Bourne, **Korn shell**, *bash*, and *zsh* shells.

Bourne Again Shell (*bash*) is the free version of the Bourne shell distributed with **Linux** systems. *Bash* is similar to the original, but has added features such as command-line editing. Its name is sometimes spelled as Bourne Again SHell, the capitalized *Hell* referring to the difficulty some people have with it.

Zsh was developed by Paul Falstad as a replacement for both the Bourne and **C shell**. It incorporates features of all the other shells (such as file name completion and a history mechanism) as well as new capabilities. *Zsh* is considered similar to the Korn shell. Falstad intended to create in *zsh* a shell that would do whatever a programmer might reasonably hope it would do. *Zsh* is popular with advanced users.

Along with the Korn shell and the C shell, the Bourne shell remains among the three most widely used and is included with all UNIX systems. The Bourne shell is often considered the best shell for developing **scripts**.

boustrophedon

Boustrophedon (from Greek for *ox-turning*) is writing that proceeds in one direction in one line (such as from left to right) and then in the reverse direction in the next line (such as from right to left). Some ancient languages, including one form of ancient Greek (650 BC), were written this way. The term derives from the way one would plow land with an ox, turning the ox back in the other direction at the end of a row. (It could be argued that boustrophedon is a more efficient way to both write and read, especially if your lines are very long.)

Some types of printers and their software print in this fashion (although the results, of course, are lines that are read in only one direction). The term is also used in describing a method used by a **raster** to scan (put the horizontal lines on) a display monitor.

brain-machine interface

In artificial intelligence (**AI**), brain-machine interface is the potential ability of the human brain to accept a mechanical device as a natural part of its representation of the body. The immediate goal of brain-machine interface study is to provide a way for people with damaged sensory/motor functions to use their brain to control artificial devices and restore lost capabilities. By combining the latest developments in computer technology and hi-tech engineering, a person suffering from paralysis might be able to control a motorized wheelchair or a prosthetic limb by just thinking about it.

Before humans can use brain-interface techniques to control artificial devices, scientists feel they must first understand how the brain gives commands. They are gaining a better understanding of how brain-interface might work by recording neurological activity over long periods of time. For instance, Duke University Medical Center researchers have tested a neural system that allows scientists to record individual neuron responses from multiple electrodes implanted in a monkey's brain. The research team was able to combine the individual neuron responses outside the monkey by running the data through a computer using an

algorithmic program. The monkey was encouraged to control its **robot** arm and reach for food. The monkey was able to successfully complete the task. Scientists were then able to use the neuron data they gathered to transmit the monkey's brain signals over the Internet in real time and control a robot arm 600 miles away. This is considered to be a major breakthrough in brain-machine interface study.

One of the biggest challenges in developing true brain-machine interface involves the development of electrode devices and surgical methods that are minimally invasive to allow safe, long-term recording of neurological activity. Duke's biomedical engineering department is now working on developing a telemetry **chip** to collect and transmit **data** through the skull without any external sockets or cables. This is expected to provide the necessary information needed to make brain-interface devices, which require deliberate conscious thought, as common as pacemakers for the heart, which work involuntarily.

brand

A brand is a product, service, or concept that is publicly distinguished from other products, services, or concepts so that it can be easily communicated and usually marketed. A brand name is the name of the distinctive product, service, or concept. Branding is the process of creating and disseminating the brand name. Branding can be applied to the entire corporate identity as well as to individual product and service names.

Brands are usually protected from use by others by securing a trademark or service mark from an authorized agency, usually a government agency. Before applying for a trademark or service mark, you need to establish that someone else hasn't already obtained one for your name. Although you can do the searching yourself, it is common to hire a law firm that specializes in doing trademark searches and managing the application process, which, in the U.S., takes about a year. Once you've learned that no one else is using it, you can begin to use your brand name as a trademark simply by stating it is a trademark (using the "TM" where it first appears in a publication or Web site). After you receive the trademark, you can use the registered ® symbol after your trademark.

Brands are often expressed in the form of *logos*, graphic representations of the brand. In computers, a recent example of widespread brand application was the "Intel Inside" label provided to manufacturers that use Intel's microchips.

A company's brands and the public's awareness of them is often used as a factor in evaluating a company. Corporations sometimes hire market research firms to study public recognition of brand names as well as attitudes toward the brands.

Here is the famous advertising copywriter and ad agency founder David Ogilvy's definition of a brand:

The intangible sum of a product's attributes: its name, packaging, and price, its history, its reputation, and the way it's advertised.

BREW

BREW (Binary Runtime Environment for Wireless) is Qualcomm's **open source** application development **platform** for **wireless** devices equipped for code division multiple access (CDMA) technology. BREW makes it possible for developers to create portable applications that will work on any handsets equipped with CDMA **chipsets**. Because BREW runs in between the application and the chip operating system software, the application can use the device's functionality without the developer needing to code to the system interface or even having to understand wireless applications. Users can download applications—such as text chat, enhanced e-mail, location positioning, games (both online and offline), and Internet radio—from carrier networks to any BREW-enabled phone.

BREW is competing for wireless software market share with **J2ME** (Java 2 Micro Edition), a similar platform from Sun Microsystems. The initial version of BREW is solely for CDMA networks; later versions could be enabled for time division multiple access (TDMA) and Global System for Mobile Communication (GSM) networks.

bricks and mortar

Bricks and mortar refers to businesses that have physical (rather than virtual or online) presences—in other words, stores (built of physical material such as bricks and mortar) that you can drive to and enter physically to see, touch, and purchase merchandise. This term is used as the basis for the term **clicks and mortar**, a business that sells products and services on the Web as well as from physical locations.

In an ongoing trend, large businesses that existed before the invention of the Web (and were therefore bricks and mortar businesses) are becoming clicks and mortar businesses. Companies like Amazon.com and others that have never owned a bricks and mortar storefront are generally known as **dotcom** companies.

bridge

In telecommunication networks, a bridge is a product that connects a local area network (LAN) to another local area network that uses the same **protocol** (for example, **Ethernet** or **token ring**). You can envision a bridge as being a device that decides whether a message from you to someone else is going to the local area network in your building or to someone on the local area network in the building across the street. A bridge examines each message on a LAN, "passing" those known to be within the same LAN, and forwarding those known to be on the other interconnected LAN (or LANs).

H
I
J
K
L
M
N
O
P
Q
R
S
T
U
V,W
X,Y,Z

In bridging networks, computer or **node** addresses have no specific relationship to location. For this reason, messages are sent out to every address on the network and accepted only by the intended destination node. Bridges learn which addresses are on which network and develop a *learning table* so that subsequent messages can be forwarded to the right network.

Bridging networks are generally always interconnected local area networks since broadcasting every message to all possible destinations would flood a larger network with unnecessary traffic. For this reason, **router** networks such as the Internet use a scheme that assigns addresses to nodes so that a message or packet can be forwarded only in one general direction rather than forwarded in all directions.

A bridge works at the data-link (physical network) level of a network, copying a data **frame** from one network to the next network along the communications path.

A bridge is sometimes combined with a router in a product called a **brouter**.

bridge disc

See "CD-Bridge Disc"

bridge disk

See "CD-Bridge Disc"

bridge tap

A bridge tap is an extraneous length of dangling, unterminated cable on a communications line, usually left over from an earlier configuration, that can cause **impedance** mismatches and other undesired effects in transmissions. In a given cabling arrangement, allowance is usually made for a certain length of bridge taps.

ISDN uses the standard line code, 2B1Q, because it has the ability to handle the incidence of bridge taps well.

brightness

Hue, saturation, and brightness are aspects of color in the red, green, and blue (**RGB**) scheme. These terms are most often used in reference to the color of each **pixel** in a cathode ray tube (**cathode ray tube**) display. All possible colors can be specified according to hue, saturation, and brightness (also called *brilliance*), just as colors can be represented in terms of the R, G, and B components.

Most sources of visible light contain energy over a band of **wavelength**. Hue is the wavelength within the visible-light spectrum at which the energy output from a source is greatest. This is shown as the peak of the curves in the accompanying graph of intensity versus wavelength. In this example, all three colors have the same hue, with a wavelength slightly longer than 500 nanometers, in the yellow-green portion of the spectrum.

Saturation is an expression for the relative **bandwidth** of the visible output from a light source. In the diagram, the saturation is represented by the steepness of the slopes of the curves. Here, the outer curve represents a color having low saturation, the middle curve represents a color having greater saturation, and the inner curve represents a color with fairly high saturation. As saturation increases, colors appear more "pure." As saturation decreases, colors appear more "washed-out."

Brightness is a relative expression of the intensity of the energy output of a visible light source. It can be expressed as a total energy value (different for each of the curves in the diagram), or as the amplitude at the wavelength where the intensity is greatest (identical for all three curves). In the RGB color model, the amplitudes of red, green, and blue for a particular color can each range from 0 to 100 percent of full brilliance. These levels are represented by the range of decimal numbers from 0 to 255, or hexadecimal numbers from 00 to FF.

British thermal unit (Btu)

A British thermal unit (Btu) is an English standard unit of **energy**. One Btu is the amount of thermal energy necessary to raise the temperature of one pound of pure liquid water by one degree Fahrenheit at the temperature at which water has its greatest density (39 degrees Fahrenheit). This is equivalent to approximately 1055 **joule** (or 1055 watt-seconds).

The Btu is often used as a quantitative specification for the energy-producing or energy-transferring capability of heating and cooling systems such as furnaces, ovens, refrigerators, and air conditioners. The heat output of

computer equipment is often specified so that it can be considered when planning the size of climate control systems in buildings. Computer device heat output is expressed in Btus per hour. 3.7 Btus per hour is equivalent to 1 watt of heat dissipation.

broadcast

Also see **bandwidth**.

In general, broadband refers to telecommunication in which a wide **band** of frequencies is available to transmit information. Because a wide band of frequencies is available, information can be multiplexed and sent on many different frequencies or channels within the band concurrently, allowing more information to be transmitted in a given amount of time (much as more lanes on a highway allow more cars to travel on it at the same time). Related terms are *wideband* (a synonym), **baseband** (a one-channel band), and **narrowband** (sometimes meaning just wide enough to carry voice, or simply “not broadband,” and sometimes meaning specifically between 50 **cps** and 64 **Kpbs**).

Various definers of *broadband* have assigned a minimum data rate to the term. Here are a few:

- Newton’s Telecom Dictionary: “...greater than a voice grade line of 3 KHz...some say [it should be at least] 20 KHz.”
- Jupiter Communications: at least 256 Kbps.
- IBM Dictionary of Computing: A broadband channel is “6 MHz wide.”

It is generally agreed that Digital Subscriber Line (**DSL**) and cable **TV** are broadband services in the downstream direction.

Broadband Integrated Services Digital Network

BISDN is both a concept and a set of services and developing standards for integrating digital transmission services in a **broadband** network of fiber optic and radio media. BISDN will encompass *frame relay* service for high-speed data that can be sent in large bursts, the Fiber Distributed-Data Interface (**FDDI**), and the Synchronous Optical Network (**SON**). BISDN will support transmission from 2 Mbps up to much higher, but as yet unspecified, rates.

BISDN is the broadband counterpart to **Integrated Services Digital Network**, which provides digital transmission over ordinary telephone company copper wires on the narrowband **local loop**.

brochureware

Also see **unicast**, **multicast**, and **anycast**.

In general, to broadcast (verb) is to cast or throw forth something in all directions at the same time. A radio or television broadcast (noun) is a program that is transmitted over airwaves for public reception by anyone with a receiver tuned to the right signal **channel**.

The term is sometimes used in e-mail or other message distribution for a message sent to all members, rather than specific members, of a group such as a department or enterprise.

On the Internet, certain **Web sites** deliver original or redistributed broadcasts from existing radio and television stations, using **streaming sound** or **streaming video** techniques, to Web users who visit the Web site or “tune it in” using a special program such as RealPlayer. Like publicly available radio and television broadcasts, Web broadcasts are available to anyone. The Web now offers live as well as prepackaged broadcasts and also plays back audio and video tapes. Some programming is scheduled and other prepackaged programs can be delivered on demand. Many Web users listen to music from a particular broadcasting site as they **surf** other sites on the Web.

Broadcast should not be confused with **unicast**, a transmission to a specific receiver (like most e-mail messages); **multicast**, a transmission to multiple specific receivers (as in e-mail to a distribution list or a Web transmission over the **MBone** network to a specific group of receiving addresses); or **anycast**, a transmission to the nearest of a group of routers, used in Internet Protocol Version 6 (**IPv6**) as a technique for chain-updating a group of routers with new routing information.

brochureware

Brochureware refers to Web sites or pages that are produced by taking an organization’s printed brochure and translating it directly to the Web without regard for the possibilities of the new medium. In extreme cases, all the copy in the brochure will be used as-is and visual images will be copied as well. The result will almost always be static and uninteresting.

Web designers usually suggest making a fresh start, using existing printed material as possible source material. While a Web site can be thought of as an “online brochure,” most designers suggest taking advantage of the Web’s interactive and dynamic capabilities, including **hypertext**, built-in programming, and **streaming video**.

brouter

A brouter (pronounced BRAU-tuhr or sometimes BEE-rau-tuhr) is a network **bridge** and a **router** combined in a single product. A bridge is a device that connects one local area network (**LAN**) to another local area network that uses the same **protocol** (for example, **Ethernet** or **token ring**). If a data unit on one LAN is intended for a destination on an interconnected LAN, the bridge forwards the data unit to that LAN; otherwise, it passes it along on the same LAN. A bridge usually offers only one path to a given interconnected LAN. A router connects a network to one or more other networks that are usually part of a wide area network (**WAN**) and may offer a number of paths to destinations on those networks. A router therefore needs to have more information than a bridge about the interconnected networks. It consults a routing table for this information. Since a given outgoing data unit or **packet** from a computer may be intended for an address on the local network, on an interconnected LAN, or the wide area network, it makes sense to have a single unit that examines all data units and forwards them appropriately.

browser

A browser is an application program that provides a way to look at and interact with all the information on the World Wide Web. The word "browser" seems to have originated prior to the Web as a generic term for user interfaces that let you browse (navigate through and read) **text** files online. By the time the first Web browser with a **graphical user interface** was available (**Mosaic**, in 1993), the term seemed to apply to Web content, too. Technically, a Web browser is a **client** program that uses the Hypertext Transfer Protocol (**HTTP**) to make requests of Web **servers** throughout the Internet on behalf of the browser user. A commercial version of the original browser, **Mosaic**, is in use. Many of the user interface features in Mosaic, however, went into the first widely-used browser, **Netscape Navigator**. Microsoft followed with its **Microsoft Internet Explorer**. Today, these two browsers are the only two browsers that the vast majority of Internet users are aware of. Although the online services, such as America Online, originally had their own browsers, virtually all now offer the Netscape or Microsoft browser. **Lynx** is a text-only browser for UNIX shell and VMS users. Another recently offered and well-regarded browser is **Opera**.

While some browsers also support e-mail (indirectly through e-mail Web sites) and the File Transfer Protocol (**FTP**), a Web browser is not required for those Internet protocols and more specialized client programs are more popular.

browserless Web

The browserless Web describes communication over the World Wide Web between programs rather than between people (with their Web **browsers**) and the server programs at Web sites. Some people believe that, within five years, program-to-program communication will generate more Internet traffic than browser-to-Web site communication. Although technically browser-to-Web site communication is program-to-program—the browser is a client program and the Web server is a server program on behalf of a Web site—the new program-to-program communication will not involve an interactive user. Such applications as ordering and order fulfillment are likely candidates for the browserless Web.

Program-to-program communication between businesses has been conducted for many years, most notably using Electronic Data Interchange (**EDI**). However, the arrival of a new data exchange technology—Extensible Markup Language (**XML**)—makes it possible for industries to develop standard names for data and for a company to easily tell other companies how its data is organized and can be accessed.

brute force cracking

Brute force (also known as brute force cracking) is a trial-and-error method used by application programs to decode encrypted data such as passwords or Data Encryption Standard (**DES**) keys, through exhaustive effort (using brute force) rather than employing intellectual strategies. Just as a criminal might break into, or "crack" a safe by trying many possible combinations, a brute force cracking application proceeds through all possible combinations of legal characters in sequence. Brute force is considered to be an infallible, although time-consuming, approach.

Crackers are sometimes used in an organization to test network security, although their more common use is for malicious attacks. Some variations, such as L0phtcrack from L0pht Heavy Industries, start by making assumptions, based on knowledge of common or organization-centered practices and then apply brute force to crack the rest of the data. L0phtcrack uses brute force to crack Windows NT passwords from a workstation. PC Magazine reported that a system administrator who used the program from a Windows 95 terminal with no administrative privileges, was able to uncover 85 percent of office passwords within twenty minutes.

BSB

See "backside bus"

BSD

BSD (originally: Berkeley Software Distribution) refers to the particular version of the **UNIX operating system** that was developed at and distributed from the University of California at Berkeley. “BSD” is customarily preceded by a number indicating the particular distribution level of the BSD system (for example, “4.3 BSD”). BSD UNIX has been popular and many commercial implementations of UNIX systems are based on or include some BSD code.

BSM

See “balanced scorecard methodology”

BSOD

See “blue screen of death”

BSP

See “business service provider”

BSRAM

See “burst SRAM”

B-tree

A B-tree is a method of placing and locating files (called records or keys) in a **database**. (The meaning of the letter B has not been explicitly defined.) The B-tree **algorithm** minimizes the number of times a medium must be accessed to locate a desired record, thereby speeding up the process.

B-trees are preferred when decision points, called nodes, are on **hard disk** rather than in random-access memory (**RAM**). It takes thousands of times longer to access a data element from hard disk as compared with accessing it from RAM, because a **disk drive** has mechanical parts, which read and write data far more slowly than purely electronic media. B-trees save time by using nodes with many branches (called children), compared with binary trees, in which each node has only two children. When there are many children per node, a record can be found by passing through fewer nodes than if there are two children per node. A simplified example of this principle is shown below.

In a tree, records are stored in locations called leaves. This name derives from the fact that records always exist at end points; there is nothing beyond them. The maximum number of children per node is the order of the tree. The number of required disk accesses is the depth. The image at left shows a binary tree for locating a particular record in a set of eight leaves. The image at right shows a B-tree of order three for locating a particular record in a set of eight leaves (the ninth leaf is unoccupied, and is called a null). The binary tree at left has a depth of four; the B-tree at right has a depth of three. Clearly, the B-tree allows a desired record to be located faster, assuming all other system parameters are

identical. The tradeoff is that the decision process at each node is more complicated in a B-tree as compared with a binary tree. A sophisticated program is required to execute the operations in a B-tree. But this program is stored in RAM, so it runs fast.

In a practical B-tree, there can be thousands, millions, or billions of records. Not all leaves necessarily contain a record, but at least half of them do. The difference in depth between binary-tree and B-tree schemes is greater in a practical database than in the example illustrated here, because real-world B-trees are of higher order (32, 64, 128, or more). Depending on the number of records in the database, the depth of a B-tree can and often does change. Adding a large enough number of records will increase the depth; deleting a large enough number of records will decrease the depth. This ensures that the B-tree functions optimally for the number of records it contains.

Also see **tree structure**. Compare **binary tree**, **M-tree**, **splay tree**, and **X-tree**.

See “chat abbreviations”

bubble help

In a computer user interface, bubble help is text information that is displayed in a small balloon or box when a computer user moves the mouse cursor over a selected user interface element, such as the iconic items in a task bar. The box (or “bubble”) is usually timed to disappear after a few seconds.

When developing a user interface with bubble help, a programmer writes code that tells the size and background color of the box, the text message to display, and when it should be removed. Bubble help is provided in most Microsoft applications, including Access and Word.

bucket brigade

A bucket brigade attack is one in which the attacker intercepts messages in a **public key exchange** and then retransmits them, substituting their own **public key** for the requested one, so that the two original parties still appear to be communicating with each other directly. The attacker uses a program that appears to be the **server** to the **client** and appears to be the client to the server. The attack may be used simply to gain access to the messages, or enable the attacker to modify them before retransmitting them. The term derives from the bucket brigade method of putting out a fire by handing buckets of water from one person to another between a water source and the fire. Another name for the bucket brigade attack is the more accurately descriptive name, man-in-the-middle, based on the ball game where a number of people try to throw a ball directly to each other while one person in between them attempts to catch it.

buckytube

See "nanotube"

buffer

A buffer is a data area shared by hardware devices or program processes that operate at different speeds or with different sets of priorities. The buffer allows each device or process to operate without being held up by the other. In order for a buffer to be effective, the size of the buffer and the algorithms for moving data into and out of the buffer need to be considered by the buffer designer. Like a **cache**, a buffer is a "midpoint holding place" but exists not so much to accelerate the speed of an activity as to support the coordination of separate activities.

This term is used both in programming and in hardware. In programming, buffering sometimes implies the need to screen data from its final intended place so that it can be edited or otherwise processed before being moved to a regular file or database.

buffer overflow

A buffer overflow occurs when a program or process tries to store more data in a **buffer** (temporary data storage area) than it was intended to hold. Since buffers are created to contain a finite amount of data, the extra information—which has to go somewhere—can overflow into adjacent buffers, corrupting or overwriting the valid data held in them. Although it may occur accidentally through programming error, buffer overflow is an increasingly common type of security attack on **data integrity**. In buffer overflow attacks, the extra data may contain codes designed to trigger specific actions, in effect sending new **instructions** to the attacked computer that could, for example, damage the user's files, change data, or disclose confidential

information. Buffer overflow attacks are said to have arisen because the **C** programming language supplied the framework, and poor programming practices supplied the vulnerability.

In July 2000, a vulnerability to buffer overflow attack was discovered in Microsoft Outlook and Outlook Express. A programming flaw made it possible for an attacker to compromise the integrity of the target computer by simply sending an e-mail message. Unlike the typical **e-mail virus**, users could not protect themselves by not opening attached files; in fact, the user did not even have to open the message to enable the attack. The programs' message header mechanisms had a defect that made it possible for senders to overflow the area with extraneous data, which allowed them to execute whatever type of code they desired on the recipient's computers. Because the process was activated as soon as the recipient downloaded the message from the server, this type of buffer overflow attack was very difficult to defend. Microsoft has since created a **patch** to eliminate the vulnerability.

bug

In computer technology, a bug is a coding error in a computer **program**. (Here we consider a program to also include the *microcode* that is manufactured into a **microprocessor**.) The process of finding bugs before program users do is called **debugging**. Debugging starts after the code is first written and continues in successive stages as code is combined with other units of programming to form a software product, such as an **operating system** or an **application**. After a product is released or during public **beta testing**, bugs are still apt to be discovered. When this occurs, users have to either find a way to avoid using the "buggy" code or get a **patch** from the originators of the code.

A bug is not the only kind of problem a program can have. It can run bug-free and still be difficult to use or fail in some major objective. This kind of flaw is more difficult to test for (and often simply isn't). It is generally agreed that a well-designed program developed using a well-controlled process will result in fewer bugs per thousands of lines of code.

The term's origin has been wrongly attributed to the pioneer programmer, **Grace Hopper**. In 1944, Hopper, a young Naval Reserve officer, went to work on the Mark I computer at Harvard, becoming one of the first people to write programs for it. As Admiral Hopper, she later described an incident in which a technician is said to have pulled an actual bug (a moth, in fact) from between two electrical relays in the Mark II computer. In his book, *The New Hacker's Dictionary*, Eric Raymond reports that the moth was displayed for many years by the Navy and is now the property of the Smithsonian. Raymond also notes that Admiral Hopper was already aware of the term when she told the moth story. The term was used prior to modern computers to mean an industrial or electrical defect.

Less frequently, the term is applied to a computer hardware problem.

bulletin board system

A bulletin board system (BBS), is a computer that can be reached by computer **modem** dialing (and, in some cases, by **Telnet**) for the purpose of sharing or exchanging messages or other files. Some BBS's are devoted to specific interests; others offer a more general service. The definitive *BBS List* says that there are 40,000 BBS's world-wide.

Among special interests represented on BBS's are dentistry, law, guns, multi-player games, Druidic practices, and information for the disabled. A significant number of BBS sites offer "adult-oriented" chat and images that can be downloaded. Many BBS's are free; some charge a membership or use fee.

Essentially, a bulletin board system is a **host** computer that is accessible by dial-up phone (you need to know the phone number) or, at some sites, via Telnet. Since calling a bulletin board system can involve long-distance charges, you may want to try starting with some in your area.

Bulletin board systems originated and generally operate independently of the Internet. However, many BBS's have Web sites. And many Internet **access providers** have bulletin board systems from which new Internet users can download the necessary software to get connected.

BBS's have their own culture and jargon. A **sysop** is the person who runs the site (many BBS's are on small home computers that have simply added the necessary software to keep track of files and users). Many BBS users chat online (see **chat abbreviations**).

burn

To burn (verb) a CD-ROM is a colloquial term meaning to write to the CD-ROM all the content that is to be put on it for a given purpose. After you've burned or burnt (either is correct) the CD-ROM, copies can be made one at a time or in multiples (the latter process is usually called duplication or replication).

burn rate

In venture investing and new company development, the burn rate is the rate at which a new company is spending its capital while waiting for profitable operation. Typically, a new company, especially in new, fast-growing fields such as Internet commerce or publishing, expects in its early stages to spend money faster than it can take in revenue. The term is often seen in financial reviews and discussions about new Internet companies, public or private, where the question is whether revenue will begin to flow in sufficient amounts before the invested capital plus revenue is "burnt up." When the burn rate begins to exceed plan or revenue fails to meet expectations, the usual recourse is to reduce the burn rate

(which, in most companies, means reducing the staff). When it is burnt up (or before), a company has to find additional capital through loans, private equity investors, or a public stock offering; merge with or sell itself to another company; go non-profit; or terminate its operation.

Michael Wolff's book, *Burn Rate* (subtitled "How I Survived the Gold Rush Years on the Internet"), describes the emotional peaks and valleys associated with the term.

BURN-Proof

BURN-Proof (Buffer Under Run Error Proof) is a technology developed by Sanyo that allows compact disc (**CD**) recording to automatically stop in the event of an unplanned interruption and then to resume recording. BURN-Proof is a registered trademark of Sanyo.

When a CD is burned (recorded), the data must usually be written onto the CD without any interruption. If an interruption, such as the opening of a new application, does occur, a Buffer Under Run error occurs and the burn is unsuccessful. BURN-Proof technology located on **firmware** inside the **CD-R** or **CD-RW** drive monitors the recording process. If the drive detects a Buffer Under Run error, it suspends recording. When the problem is resolved, the CD-R or CD-RW drive restarts recording data from where it stopped.

BURN-Proof technology is used with CD drive speeds **12x** and higher because Buffer Under Run errors occur more often with faster drives. Many CD recording application vendors provide BURN-Proof support with their software.

burst

Burst is a term used in a number of information technology contexts to mean a specific amount of data sent or received in one intermittent operation. It can be contrasted with *streamed*, *paced*, or *continuous*. Generally, a burst operation implies that some threshold has been reached that triggers the burst. Depending on the particular technology, a burst operation can be intermittent at a regular or an irregular rate.

Burst Extended Data Output DRAM

See "BEDO DRAM"

burst SRAM

Burst SRAM is used as the external **L1 and L2** memory for the **Pentium** microprocessor chipset. Burst SRAM (also known as SynchBurst **SRAM**) is synchronized with the system clock or, in some cases, the cache bus clock. This allows it be more easily synchronized with any device that accesses it and reduces access waiting time.

bus

In a computer or on a network, a bus is a transmission path on which **signals** are dropped off or picked up at every device attached to the line. Only devices addressed by the signals pay attention to them; the others discard the signals. According to Winn L. Rosch, the term derives from its similarity to autobuses that stop at every town or block to drop off or take on riders

In general, the term is used in two somewhat different contexts:

1) A bus is a network topology or circuit arrangement in which all devices are attached to a line directly and all signals pass through each of the devices. Each device has a unique identity and can recognize those signals intended for it.

2) In a computer, a bus is the data path on the computer's **motherboard** that interconnects the microprocessor with attachments to the motherboard in expansion slots (such as hard disk drives, CD-ROM drives, and graphics adapters).

bus master

A bus master is the program, either in a microprocessor or more usually in a separate I/O controller, that directs traffic on the computer **bus** or input/output paths. The bus master is the "master" and the I/O devices on the bus are the "slaves." The bus master actually controls the bus paths on which the address and control signals flow. Once these are set up, the flow of data bits goes directly between the I/O device and the microprocessor.

Bush, Vannevar

See "Vannevar Bush"

business intelligence

Business intelligence (BI) is a broad category of **applications** and technologies for gathering, storing, analyzing, and providing access to **data** to help **enterprise** users make better business decisions. BI applications include the activities of **decision support systems**, query and reporting, online analytical processing (OLAP), statistical analysis, forecasting, and **data mining**.

Business intelligence applications can be:

- Mission-critical and integral to an enterprise's operations or occasional to meet a special requirement
- Enterprise-wide or local to one division, department, or project
- Centrally initiated or driven by user demand

This term was used as early as September, 1996, when a Gartner Group report said:

By 2000, Information Democracy will emerge in forward-thinking enterprises, with Business Intelligence information and applications available broadly to employees, consultants, customers, suppliers, and the public. The key to thriving in a competitive marketplace is staying ahead of the competition. Making sound business decisions based on accurate and current information takes more than intuition. Data analysis, reporting, and query tools can help business users wade through a sea of data to synthesize valuable information from it—today these tools collectively fall into a category called "Business Intelligence."

Business Planning and Control System

Business Planning and Control System (BPCS) is a popular system of **application programs** for manufacturing and other industries that is developed and sold by Systems Software Associates (SSA). SSA reports that BPCS is installed at over 8,000 business sites worldwide. The BPCS applications are divided into:

- Configurable enterprise financials (including accounts receivable and payable, cost accounting, remittance processing, and budgeting and analysis)
- Supply chain management applications (including sale performance management, purchasing, promotion, inventory management, and forecasting)
- Multi-mode manufacturing applications (including planning, production scheduling, capacity planning, shop floor control, and plant maintenance)

The key ideas in BPCS include:

- A general adherence to programming standards for distributed object computing (including **Common Object Request Broker Architecture**) and other standards
- A sophisticated use of **client/server** computing and **object** data repositories
- Adoption of the Microsoft Windows Desktop user interface for all end users site-wide
- A guided workstation-based system of installation

SSA augments its own sales and support force with a system of independent business associates. It has a widely-distributed customer base, with 34% of its customers in Europe, 22% in the Asia Pacific region, and 10% in Latin America.

Business Process Management Initiative

Established in August 2000, the Business Process Management Initiative (BPMI) is a non-profit organization that exists to promote the standardization of common business processes, as a means of furthering **e-business** and **B2B** development. BPMI was founded by a group of 16 e-business industry leaders: Aventail, Black Pearl, Blaze

Software, Bowstreet, Cap Gemini Ernst & Young, Computer Sciences Corporation, Cyclone Commerce, DataChannel, Entricom, Intalio, Ontology.Org, S1 Corporation, Versata, VerticalNet, Verve, and XMLFund. Since its inception, the group has grown to include more than 80 companies. BPMI's stated **mission** is "to promote and develop the use of Business Process Management (BPM) through the establishment of standards for process design, deployment, execution, maintenance, and optimization." By so doing, BPMI intends to make it much easier for enterprises to interact and to further develop the global marketplace. Currently, e-business reflects the idiosyncratic ways that business processes work within an organization. There are, for example, different names for the same item, and incompatible processes across organizations. The goal of BPMI is to overcome these problems and make it possible for organizations to communicate more effectively and share not only data, but applications.

The BPMI model of any two-way e-business process involves three main components, the *public interface* and two *private implementations*. The public interface, which is the area of interaction between two business partners, is supported by various protocols such as those associated with **BizTalk**, **ebXML**, and **RosettaNet**. The model further defines two private implementations, which are specific to the individual partners involved and can be described in any executable language. The Initiative has specified such a language, Business Process Modeling Language (**BPML**), which is an XML-based **metalanguage** that can be used to model components of business processes in the same way that XML can be used to model components of business data. An associated **query** language, BPQL (Business Process Query Language) has been developed by Initiative members as a standard management interface that can be used to deploy and execute defined business processes. Both BPML and BPQL are open specifications; BPML is available for download from the BPMI Web site. The organization intends to continue to develop and promote open standards specific to particular e-business needs.

Business Process Modeling Language

Business Process Modeling Language (BPML) is an Extensible Markup Language (XML)-based **metalanguage** developed by the Business Process Management Initiative (**BPMI**) as a means of modeling business processes, such as XML is, itself, a metalanguage with the ability to model enterprise data. BPML 0.4 is BPMI's first release, and includes specifications for **transactions** and compensating transactions, dataflow, **messages** and scheduled events, business rules, security roles, and exceptions. BPMI has identified three crucial aspects of BPML capability: Because it will be used for **mission critical** applications, it must support both **synchronous** and **asynchronous distributed** transactions; because it will model business processes deployed over the Internet, it must offer reliable security

mechanisms; and because it will be used throughout integrated development environments, it must encompass project management capabilities.

An associated **query** language, Business Process Query Language (**BPQL**) has been developed by Initiative members as a standard management interface that can be used to deploy and execute defined business processes. According to BPMI, BPML and BPQL will be used to establish a standardized means of managing e-business processes through *Business Process Management Systems*, similarly to the way that **SQL** established a standardized means of managing business data through packaged database management systems (**DBMSs**). Both BPML and BPQL are open specifications. The first draft of the BPML specification was submitted to BPMI members in August 2000, and subsequently made publicly available in March 2001; the first BPQL draft is to be made available by the end of 2001. The organization intends to continue to develop and promote open standards specific to particular **e-business** needs.

business process reengineering

Business process reengineering (BPR) is the analysis and redesign of **workflow** within and between enterprises. BPR reached its heyday in the early 1990's when Michael Hammer and James Champy published their best-selling book, "Reengineering the Corporation." The authors promoted the idea that sometimes radical redesign and reorganization of an **enterprise** (wiping the slate clean) was necessary to lower costs and increase quality of service and that **information technology** was the key enabler for that radical change. Hammer and Champy felt that the design of workflow in most large corporations was based on assumptions about technology, people, and organizational goals that were no longer valid. They suggested seven principles of reengineering to streamline the work process and thereby achieve significant levels of improvement in quality, time management, and cost:

1. Organize around outcomes, not tasks.
2. Identify all the processes in an organization and prioritize them in order of redesign urgency.
3. Integrate information processing work into the real work that produces the information.
4. Treat geographically dispersed resources as though they were centralized.
5. Link parallel activities in the workflow instead of just integrating their results.
6. Put the decision point where the work is performed, and build control into the process.
7. Capture information once and at the source.

By the mid-1990's, BPR gained the reputation of being a nice way of saying "**downsizing**." According to Hammer, lack of sustained management commitment and leadership,

unrealistic scope and expectations, and resistance to change prompted management to abandon the concept of BPR and embrace the next new methodology, enterprise resource planning (ERP).

business service provider

A business service provider (BSP) is a company that rents third-party software **application** packages to their customers. A BSP is similar to an application service provider (ASP) in that it provides a cost-effective way to procure applications via networks. A BSP differs from an ASP in that it tailors a software package to its customer's needs and offers back-office solutions by **outsourcing** most (if not all) business processes, such as payroll and bookkeeping. Small and mid-sized firms are attracted to BSPs because they have low start-up costs and low monthly fees, whereas ASPs are more capital intensive. Agillon, eAlity, Employeease and EConvergent are examples of successful BSP companies.

business-to-business

See "B2B"

bypass

Bypass, in general, means either *to go around something by an external route rather than going through it*, or the means of accomplishing that feat. In network security, a bypass is a flaw in a security system that allows an attacker to circumvent security mechanisms to get system or network access. The actual point of entry is through a mechanism (either a hardware device or program, even just a piece of code) that enables the user to access the system without going through the security clearance procedures (such as **authentication**) that were set up by the system administrator. A bypass may be a mechanism put in place by an attacker, a flaw in the design, or an alternate access route left in place by developers. A bypass that is purposefully put in place as a means of access for authorized users is called a *back door* or a *trap door*. A *crypto bypass* is a flaw that allows data to circumvent the **encryption** process and escape, unencrypted, as **plaintext**.

byte

In most computer systems, a byte is a unit of data that is eight **binary** digits long. A byte is the unit most computers use to represent a character such as a letter, number, or typographic symbol (for example, "g", "5", or "?"). A byte can also hold a string of bits that need to be used in some larger unit for application purposes (for example, the stream of bits that constitute a visual image for a program that displays images or the string of bits that constitutes the machine code of a computer program).

In some computer systems, four bytes constitute a **word**, a unit that a computer processor can be designed to handle efficiently as it reads and processes each instruction. Some computer processors can handle two-byte or single-byte instructions.

A byte is abbreviated with a "B". (A bit is abbreviated with a small "b".) Computer storage is usually measured in byte multiples. For example, an 820 MB hard drive holds a nominal 820 million bytes—or megabytes—of data. Byte multiples are based on powers of 2 and commonly expressed as a "rounded off" decimal number. For example, one megabyte ("one million bytes") is actually 1,048,576 (decimal) bytes. (Confusingly, however, some hard disk manufacturers and dictionary sources state that bytes for computer storage should be calculated as powers of 10 so that a megabyte really would be one million decimal bytes.)

Some language scripts require two bytes to represent a character. These are called double-byte character sets (DBCS).

According to Fred Brooks, an early hardware architect for IBM, project manager for the OS/360 operating system, and author of *The Mythical Man-Month*, Dr. Werner Buchholz originated the term *byte* in 1956 when working on IBM's STRETCH computer.

Also see **megabyte**, **gigabyte**, **terabyte**, **petabyte**, and **exabyte**.

byte code

See "bytecode"

bytecode

Bytecode is computer **object code** that is processed by a program, usually referred to as a **virtual machine**, rather than by the "real" computer machine, the hardware **processor**. The virtual machine converts each generalized machine **instruction** into a specific machine instruction or instructions that this computer's processor will understand. Bytecode is the result of compiling source code written in a language that supports this approach. Most computer languages, such as C and C++, require a separate **compiler** for each computer **platform**—that is, for each computer **operating system** and the hardware set of instructions that it is built on. Windows and the Intel line of microprocessor architectures are one platform; Apple and the PowerPC processors are another. Using a language that comes with a virtual machine for each platform, your source language statements need to be compiled only once and will then run on any platform.

The best-known language today that uses the bytecode and virtual machine approach is **Java**. The **LISP** language, used in artificial intelligence applications, is an earlier language that compiled bytecode. Other languages that use bytecode or a similar approach include Icon and Prolog.

Rather than being interpreted one instruction at a time, Java bytecode can be recompiled at each particular system platform by a **just-in-time compiler**. Usually, this will enable the Java program to run faster. In Java, bytecode is contained in a **binary file** with a .CLASS suffix.

C

C is a structured, procedural programming language that has been widely used both for operating systems and applications and that has had a wide following in the academic community. Many versions of UNIX-based operating systems are written in C. C has been standardized as part of the Portable Operating System Interface (POSIX).

With the increasing popularity of **object-oriented programming**, C is being rapidly replaced as “the” programming language by C++, a superset of the C language that uses an entirely different set of programming concepts, and by **Java**, a language similar to but simpler than C++, that was designed for use in distributed networks.

C sharp

See “C#”

C shell

C shell is the **UNIX shell** (command execution program, often called a *command interpreter*) created by Bill Joy at the University of California at Berkeley as an alternative to UNIX’s original shell, the **Bourne shell**. These two UNIX shells, along with the **Korn shell**, are the three most commonly used shells. The C shell program name is *cs*, and the shell prompt (the character displayed to indicate readiness for user input) is the % symbol. The C shell was invented for programmers who prefer a **syntax** similar to that of the C programming language.

The other popular member of the C shell family is called *tcsh* (for Tab C shell) and is an extended version of C shell. Some of *tcsh*’s added features are: enhanced *history substitution* (which allows you to reuse commands you have already typed), spelling correction, and *word completion* (which allows you to type the first couple of letters in a word and hit the tab key to have the program complete it).

Once considered “buggy”, the C shell has had a number of different versions developed to overcome the flaws in the original program. Most often, only experienced users prefer to use the C shell. C is frequently the default shell at universities and research organizations and is the default on many systems, especially those derived from Berkeley UNIX.

C#

C# (pronounced “C-sharp”) is a new **object-oriented programming** language from Microsoft, which aims to combine the computing power of C++ with the programming ease of **Visual Basic**. C# is based on C++ and contains features similar to those of **Java**.

C# is designed to work with Microsoft’s .Net platform. Microsoft’s aim is to facilitate the exchange of information and services over the Web, and to enable developers to build highly **portable** applications. C# simplifies programming through its use of Extensible Markup Language (XML) and Simple Object Access Protocol (SOAP) which allow access to a programming **object** or **method** without requiring the programmer to write additional code for each step. Because programmers can build on existing code, rather than repeatedly duplicating it, C# is expected to make it faster and less expensive to get new products and services to market.

Microsoft is collaborating with ECMA, the international standards body, to create a standard for C#. International Standards Organization (ISO) recognition for C# would encourage other companies to develop their own versions of the language. Companies that are already using C# include Apex Software, Bunka Orient, Component Source, devSoft, FarPoint Technologies, LEAD Technologies, ProtoView, and Seagate Software.

C++

C++ is an object-oriented programming (**OOP**) language that is viewed by many as the best language for creating large-scale applications. C++ is a superset of the C language.

A related programming language, **Java**, is based on C++ but optimized for the distribution of program objects in a network such as the Internet. Java is somewhat simpler and easier to learn than C++ and has characteristics that give it other advantages over C++. However, both languages require a considerable amount of learning time.

C2

See “Class C2”

C3D

C3D (pronounced SEE-THREE-DEE) is a combined hardware/software process that captures a pair of two-dimensional images, objects, or scenes and automatically reconstructs them into a digital three-dimensional (**3-D**) model. In turn, this model can be used to create a **virtual** representation of the image, object, or scene. The C3D process uses a standard PC and camera to produce a realistic photographic model for viewing on a PC at a reconstruction accuracy of 50 **microns**. C3D can be used with other tools, such as the Virtual Reality Modelling Language (**VRML**).

C3D exploits the stereoptic function of the human brain, which is able to combine an image perceived by each eye into a 3-D perception. Capturing images using the C3D process allows the image to be manipulated horizontally,

vertically, or spatially (that is, by distance) using one of three modelling representations: a polygon wire frame, shaded, or naturally rendering. Once you create the modeling representation, a photographic rendering from the image pairing is placed on the modelling representation to create the shaped model.

Current C3D application uses include: tire footprints, health care studies, police mugshots, virtual studio applications for TV, microscopic modelling objects, aerial road surveys, and museum artifact archiving.

C6

See “WinChip”

CA

See “certificate authority”

CAB

See “cabinet file”

cabinet file

In Microsoft program development, a cabinet is a single file created to hold a number of compressed files. A related set of cabinet files can be contained in a folder. During installation of a program, the compressed files in a cabinet are decompressed and copied to an appropriate directory for the user. A cabinet file usually has the file name **suffix** of “.cab”.

Microsoft uses cabinet files in distributing its own products, such as PowerPoint, Microsoft Office for Windows, and Microsoft Money. Cabinet files save space and time during software distribution. They are decompressed during installation. Large files can be compressed and included in more than one cabinet file, each of which logically points to the next file, with all contained in a logical folder.

Development accountability for cabinet files is ensured by providing a signed digital certificate with the cabinet file. One “signature” covers all the files in a cabinet file. Cabinet files are created using Lempel-Ziv compression.

cable

See “coaxial cable”

cable head-end

A cable head-end is the facility at a local cable TV office that originates and communicates **cable TV** services and **cable modem** services to subscribers. In distributing cable television services, the head-end includes a satellite dish **antenna** for receiving incoming programming. This programming is then passed on to the subscriber. (Cable TV companies may also play videotapes and originate live programming.) Normally, all signals are those that are sent

downstream to the subscriber, but some are received upstream such as when a customer requests a **pay-per-view** program.

When a cable company provides Internet access to subscribers, the head-end includes the computer system and databases needed to provide Internet access. The most important component located at the head-end is the cable modem termination system (**CMTS**), which sends and receives digital cable modem signals on a cable network and is necessary for providing Internet services to cable subscribers.

cable modem

A cable modem is a device that enables you to hook up your PC to a local **cable TV** line and receive data at about 1.5 **Mbps**. This data rate far exceeds that of the prevalent 28.8 and 56 Kbps telephone modems and the up to 128 Kbps of Integrated Services Digital Network (**ISDN**) and is about the data rate available to subscribers of Digital Subscriber Line (**DSL**) telephone service. A cable modem can be added to or integrated with a **set-top box** that provides your TV set with channels for Internet access. In most cases, cable modems are furnished as part of the cable access service and are not purchased directly and installed by the subscriber.

A cable modem has two connections: one to the cable wall outlet and the other to a PC or to a set-top box for a TV set. Although a cable modem does **modulate** between **analog** and **digital** signals, it is a much more complex device than a telephone **modem**. It can be an external device or it can be integrated within a computer or set-top box. Typically, the cable modem attaches to a standard **10BASE-T Ethernet card** in the computer.

All of the cable modems attached to a cable TV company **coaxial cable** line communicate with a cable modem termination system (CMTS) at the local cable TV company office. All cable modems can receive from and send signals only to the CMTS, but not to other cable modems on the line. Some services have the upstream signals returned by telephone rather than cable, in which case the cable modem is known as a *telco-return* cable modem.

The actual **bandwidth** for Internet service over a cable TV line is up to 27 Mbps on the download path to the subscriber with about 2.5 Mbps of bandwidth for interactive responses in the other direction. However, since the local provider may not be connected to the Internet on a line faster than a **T-carrier system** at 1.5 Mbps, a more likely data rate will be close to 1.5 Mbps.

Leading companies using cable TV to bring the Internet to homes and businesses are @Home and Time-Warner.

In addition to the faster data rate, an advantage of cable over telephone Internet access is that it is a continuous connection.

cable modem termination system

A cable modem termination system (CMTS) is a component that exchanges digital signals with **cable modems** on a cable network. A cable modem termination system is located at the local office of a cable television company.

A data service is delivered to a subscriber through **channels** in a **coaxial cable** or **optical fiber** cable to a cable modem installed externally or internally to a subscriber's **computer** or television set. One television channel is used for upstream signals from the cable modem to the CMTS, and another channel is used for downstream signals from the CMTS to the cable modem. When a CMTS receives signals from a cable modem, it converts these signals into Internet Protocol (IP) **packets**, which are then sent to an IP **router** for transmission across the Internet. When a CMTS sends signals to a cable modem, it **modulates** the downstream signals for transmission across the cable to the cable modem. All cable modems can receive from and send signals to the CMTS but not to other cable modems on the line.

cable TV

Cable TV is also known as "CATV" (community antenna television). In addition to bringing television programs to those millions of people throughout the world who are connected to a community antenna, cable TV will likely become a popular way to interact with the World Wide Web and other new forms of multimedia information and entertainment services.

Also see **cable modem**, **interactive TV**, and **WebTV**.

CableLabs Certified Cable Modems

See "DOCSIS"

cache

A cache (pronounced CASH) is a place to store something more or less temporarily. Web pages you request are stored in your browser's cache directory on your hard disk. That way, when you return to a page you've recently looked at, the browser can get it from the cache rather than the original server, saving you time and the network the burden of some additional traffic. You can usually vary the size of your cache, depending on your particular browser.

Computers include caches at several levels of operation, including **cache memory** and a **disk cache**. Caching can also be implemented for Internet content by distributing it to multiple servers that are periodically refreshed. (The use of the term in this context is closely related to the general concept of a distributed information base.)

Altogether, we are aware of these types of caches:

- International, national, regional, organizational and other "macro" caches to which highly popular information can be distributed and periodically updated and from which most users would obtain information.
- Local server caches (for example, corporate LAN servers or access provider servers that cache frequently accessed files). This is similar to the previous idea, except that the decision of what data to cache may be entirely local.
- Your Web **browser's** cache, which contains the most recent Web files that you have downloaded and which is physically located on your hard disk (and possibly some of the following caches at any moment in time).
- A **disk cache** (either a reserved area of RAM or a special hard disk cache) where a copy of the most recently accessed data and adjacent (most likely to be accessed) data is stored for fast access.
- RAM itself, which can be viewed as a cache for data that is initially loaded in from the hard disk (or other I/O storage systems).
- L2 **cache memory**, which is on a separate chip from the microprocessor but faster to access than regular RAM.
- L1 cache memory on the same chip as the microprocessor.

Also see: **buffer**, which, like a cache, is a temporary place for data, but with the primary purpose of coordinating communication between programs or hardware rather than improving process speed.

cache coherence

In a shared memory **multiprocessor** with a separate **cache memory** for each **processor**, it is possible to have many copies of any one instruction **operand**: one copy in the main memory and one in each cache memory. When one copy of an operand is changed, the other copies of the operand must be changed also. Cache coherence is the discipline that ensures that changes in the values of shared operands are propagated throughout the system in a timely fashion.

There are three distinct levels of cache coherence:

1. Every write operation appears to occur instantaneously.
2. All processes see exactly the same sequence of changes of values for each separate operand.
3. Different processes may see an operand assume different sequences of values. (This is considered noncoherent behavior.) In both level 2 behavior and level 3 behavior, a program can observe **stale data**. Recently, computer designers have come to realize that the programming discipline required to deal with level 2 behavior is sufficient to deal also with level 3 behavior. Therefore, at some point only level 1 and level 3 behavior will be seen in machines.

cache engine

See “cache server”

cache memory

Cache memory is random access memory (**RAM**) that a computer **microprocessor** can access more quickly than it can access regular RAM. As the microprocessor processes data, it looks first in the **cache** memory and if it finds the data there (from a previous reading of data), it does not have to do the more time-consuming reading of data from larger **memory**.

Cache memory is sometimes described in levels of closeness and accessibility to the microprocessor. An **L1** cache is on the same chip as the microprocessor. (For example, the **PowerPC 601** processor has a 32 kilobyte level-1 cache built into its chip.) **L2** is usually a separate static RAM (**SRAM**) chip. The main RAM is usually a dynamic RAM (**DRAM**) chip.

In addition to cache memory, one can think of RAM itself as a cache of memory for **hard disk** storage since all of RAM's contents come from the hard disk initially when you turn your computer on and load the operating system (you are loading it into RAM) and later as you start new applications and access new data. RAM can also contain a special area called a **disk cache** that contains the data most recently read in from the hard disk.

cache server

A cache server (sometimes called a cache engine) is a **server** relatively close to Internet users and typically within a business enterprise that saves (**caches**) Web pages and possibly FTP and other files that all server users have requested so that successive requests for these pages or files can be satisfied by the cache server rather than requiring the user of the Internet. A cache server not only serves its users by getting information more quickly but also reduces Internet traffic.

A cache server is almost always also a **proxy server**, which is a server that “represents” users by intercepting their Internet requests and managing them for users. Typically, this is because enterprise resources are being protected by a **firewall** server that allows outgoing requests to go out but needs to screen all incoming traffic. A proxy server helps match incoming messages with outgoing requests and is in a position to also cache the files that are received for later recall by any user. To the user, the proxy and cache servers are invisible; all Internet requests and returned responses appear to be coming from the addressed place on the Internet. (The proxy is not quite invisible; its IP address has to be specified as a configuration option to the browser or other protocol program.)

CAD

CAD (computer-aided design) software is used by architects, engineers, drafters, artists, and others to create precision drawings or technical illustrations. CAD software can be used to create two-dimensional (2-D) drawings or three-dimensional (3-D) models.

CAD/CAM (computer-aided design/computer-aided manufacturing) is software used to design products such as electronic circuit boards in computers and other devices.

CAD/CAM

CAD/CAM (computer-aided design/computer-aided manufacturing) is software used to design products such as electronic circuit boards in computers and other devices.

call center

A call center is a central place where customer and other telephone calls are handled by an organization, usually with some amount of computer automation. Typically, a call center has the ability to handle a considerable volume of calls at the same time, to screen calls and forward them to someone qualified to handle them, and to log calls. Call centers are used by mail-order catalog organizations, telemarketing companies, computer product help desks, and any large organization that uses the telephone to sell or service products and services.

call failure rate

Call failure rate (CFR) is a statistical measure commonly used in assessing Internet Service Providers (**ISPs**) or any network provider. The call failure rate is the percentage of calls to an ISP or network provider that fail to get through. Companies can measure the CFR for their own employees who dial in for access to the company's network. Rating companies report on the CFRs for major ISPs like AOL, Ameritech, and Mindspring. Visual Networks, formerly Inverse Network Technology, is probably the best known benchmarking company of ISPs.

callback

Callback, also known as *international callback*, is a system for avoiding regular phone company long-distance charges by having a call initiated from within the U.S. with the originating caller joining in a conference call. Here's how the procedure works:

- A call originator (for example, someone in South America) calls a predesignated number in the U.S., waits until it rings once, and then hangs up.
- A machine in the office where the phone rang recognizes that the phone number was called and knows the phone number of the party that called it (because it was the only party that knew the number).

G

H

I

J

K

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

- The machine places a call (which may be a local or a long-distance call) that originates from the U.S. location and also calls the party who initiated this procedure, thus arranging a conference call but at the U.S. long-distance rate.
- In another variation, the automatically-generated call from the U.S. may call the originator and ask the originator to dial their desired number or provide a U.S. dial tone.
- The originator (who subscribes to this callback service) is billed by the U.S.-based service at its own rates.

In localities where portable phone (cellphone) companies do not charge for incoming calls, callback is also sometimes used to avoid airtime charges for outgoing calls.

CallXML

CallXML is a language based on the Extensible Markup Language (XML) that lets a company describe a phone-to-Web site application in terms of how the call would be handled at the Web site and how it would interact with the caller based on keyed-in or voice responses. CallXML is similar to other voice markup languages such as VoiceXML and Microsoft's WTE.

Basically, CallXML is used to describe the user interface of a telephone, VoIP, or multimedia application to a CallXML browser. A CallXML browser then uses that description to control and react to the call itself. According to a Voxeo, a vendor that supports CallXML, the markup language includes:

- Media action elements such as "playAudio" and "recordAudio" to describe what to be presented to the user during a call
- Call action elements such as "answer," "call" and "hangup" to describe how to control and route the call
- Logic action elements such as "assign," "clear," and "goto" to describe how to modify variables and interact with traditional server-side Web logic such as Perl, other CGI languages, PHP or ASP
- Event elements such as "onTermDigit," "onHangup" to describe how to react to things the user can do during the call, such as pressing digits or hanging up
- Block elements that logically group actions & events together, so that one set of event handling elements can be used for several sequential actions

Whereas VoiceXML, another computer telephony language, is used with voice-based applications that provide access to Web content and information, CallXML aims to make it easy for Web developers to create applications that can interact with and control any number or type of calls. VoiceXML 1.0 was created through a collaboration of AT&T, IBM, Lucent Technologies, and Motorola.

calm technology

In computing, calm technology aims to reduce the "excitement" of information overload by letting the user select what information is at the center of their attention and what information is peripheral. The term was coined by Mark Weiser, chief technologist, and John Seeley Brown, director of the Xerox Palo Alto Research Lab. In the coming age of *ubiquitous computing* in which technology will become at once pervasive yet invisible, Weiser and Brown foresee the need for design principles and methods that enable users to sense and control what immediately interests them while retaining peripheral awareness of other information possibilities that they can at any time choose to focus on. Calm technology, they envision, will not only relax the user but, by moving unneeded information to the edge of an interface, allow more information to exist there, ready for selection when needed. An example: A video conference may be a calmer interface than a phone conference because the explicit visual knowledge of details that are peripheral gives participants more confidence in what can be focused on and what can be left at the edge. (Think of phone conferences in which participants are never quite sure who has entered or left the room at the other end. This lack of information is not necessarily calming!) Knowledge of the periphery gives us "locatedness" without unduly distracting us.

As another example of calm technology, Weiser and Brown cite inner office windows. An office occupant can choose to focus on work within the office while maintaining some low level of awareness of the larger environment as people are seen moving in the office aisles. From the aisle, a worker has a sense of who is or isn't at work in their office. Weiser and Brown see this example as a metaphor for the Internet in which people can locate and be located by others in cyberspace while maintaining various degrees of control over their privacy and the timing in which they are willing to communicate.

As devices with embedded programming become an all-pervasive part of our environment (see **micro-electromechanical systems**), the ability to design encalming devices and environments is apt to become much more important.

cam

A cam, homecam, or Webcam is a video camera, usually attached directly to a computer, whose current or latest image is requestable from a Web site. A live cam is one that is continually providing new images that are transmitted in rapid succession or, in some cases, in streaming video. Sites with live cams sometimes embed them as **Java applets** in Web pages. Cams have caught on; there are now (we estimate) several thousand sites with cams. The first cams were positioned mainly on fish tanks and coffee machines. Many of today's live cams are on sex-oriented sites. For

travel promotion, traffic information, and the remote visualization of any ongoing event that's interesting, webcams seem like an exciting possibility that will become more common as users get access to more **bandwidth**.

camcorder

A camcorder is a portable electronic recording device that is capable of recording live-motion video and audio for later replay through VCRs, TVs, and, in some models, a personal computer. Compounded from "camera" and "recorder," the term originated in the early 1980s. Camcorders are also called *video recorders*. Ordinary consumers use camcorders to film home movies of special events or vacations. Professionals such as professional videographers and filmmakers use camcorders along with other editing and film studio equipment to produce video segments or films for commercial sale.

Camcorders come in an assortment of formats, features, and price ranges. When they first arrived, camcorders recorded in one of two analog formats, VHS and Betamax formats, onto video cassettes for replay from the most popular VCRs. These camcorders often produce less than ideal quality images and earlier models can be large and cumbersome to use.

As technology improved, other formats became available, such as S-VHS, 8mm, Hi-8, and DV (digital video). Many of these formats offer a clearer, sharper picture over the original formats, and, in some cases, allow more hours of recording on a single tape than previously. These types often require an adapter for playback from a TV or VCR.

With the latest digital camcorders, many now are capable of being connected directly to a personal computer, using an i.LINK (IEEE 1394) or **FireWire** digital interface, so that the video can be edited directly on the computer for more professional results. The personal computer must be equipped with the right video editing software, a digital video capture board, and with i.Link/FireWire ports.

Camcorder features for a prospective buyer to consider include: horizontal image resolution, the size and quality of the **liquid crystal display** monitor for quick viewing as you record, the types of zooms and lenses available, and the actual size and comfort of the equipment. Leading camcorder manufacturers include Canon, Sony, JVC, Panasonic, and Sharp.

campus

In telecommunications, a campus is a physically contiguous association of locations such as several adjacent office buildings. Typically, such areas require one or more local area networks and bridging, routing, and aggregation equipment based on situational needs.

cancelbot

A cancelbot is a program or **bot** (robot) that sends a message to one or more **Usenet** newsgroups to cancel (remove from posting) a certain type of message. It searches for messages matching a certain pattern, whether it be a duplicate message or offensive material, and sends out cancels for them. When a message has been canceled, its status is changed to "cancel," and the Usenet servers will no longer post them.

Some Usenet users consider cancelbots a form of censorship. Many Usenet newsgroup administrators, however, believe that they have a right to cancel material they consider to be offensive or unwanted, such as **spam** (bulk mail). Anyone with authority to send a cancelbot has to be careful to make sure that they don't cancel more messages than they intended to.

candela

The candela (abbreviation, cd) is the standard unit of luminous intensity in the International System of Units (SI). It is formally defined as the magnitude of an **electromagnetic field**, in a specified direction, that has a power level of $\frac{1}{683}$ watt (1.46×10^{-3} W) per steradian at a frequency of 540 terahertz (540 THz or 5.40×10^{14} Hz).

Originally, luminous intensity was measured in terms of units called candles. This expression arose from the fact that one candle represented approximately the amount of visible radiation emitted by a candle flame. This was an inexact specification because burning candles vary in brilliance. So, for a time, a specified amount of radiation from elemental platinum at its freezing temperature was used as the standard. Late in the 20th century, the current definition and terminology were adopted.

The quantities comprising the specification of the candela are obscure to some non-scientists. An **EM-field** power level of 1.46×10^{-3} W is small; the radio-frequency (RF) output of a children's toy two-way radio is several times that much. A frequency of 540 THz corresponds to a wavelength of about 556 nanometers (nm), which is in the middle of the visible-light spectrum. A steradian is the standard unit solid angle in three dimensions; a sphere encloses 4 pi (approximately 12.57) steradians.

candela per meter squared

The candela per meter squared (cd/m^2) is the standard unit of luminance. It represents a luminous intensity of one candela radiating from a surface whose area is one square meter.

Formally, the candela is defined as the magnitude of an electromagnetic field (**EM field**), in a specified direction, that has a power level of $\frac{1}{683}$ **watt** (1.46×10^{-3} W) per **steradian** at a frequency of 540 **terahertz** (540 THz or 5.40×10^{14} Hz). This is in the middle of the visible-light spectrum.

V,W

X,Y,Z

Luminance is sometimes quoted when specifying the brightness of computer displays. Cathode-ray tube (CRT) monitors generally provide greater luminance than thin-film transistor (TFT) displays. However, the best criterion for choosing and adjusting a display is the user's own viewing comfort. This will depend on the level of illumination in the room where the display is used.

Also see **candela**, **meter squared**, **steradian**, and **SI** (International System of Units).

canonical

In programming, canonical means "according to the rules." And non-canonical means "not according to the rules." In the early Christian church, the "canon" was the officially chosen text. In *The New Hacker's Dictionary*, Eric Raymond tells us that the word meant "reed" in its Greek and Latin origin, and a certain length of reed came to be used as a standard measure. In some knowledge areas, such as music and literature, the "canon" is the body of work that everyone studies.

The terms are sometimes used to distinguish whether a programming interface follows a particular standard or precedent or whether it departs from it.

CAP

CAP (carrierless amplitude/phase) modulation was the original approach for **modulation** of a Digital Subscriber Line (DSL) **signal**. Discrete multitone (DMT) is now the preferred modulation alternative over CAP.

CAP is closely related to quadrature amplitude modulation (QAM).

capacitance

See "capacitor"

capacitor

A capacitor is a passive electronic component that stores energy in the form of an electrostatic field. In its simplest form, a capacitor consists of two conducting plates separated by an insulating material called the **dielectric**. The capacitance is directly proportional to the surface areas of the plates, and is inversely proportional to the separation between the plates. Capacitance also depends on the dielectric constant of the substance separating the plates.

The standard unit of capacitance is the **farad**, abbreviated F. This is a large unit; more common units are the microfarad, abbreviated μF ($1 \mu\text{F} = 10^{-6} \text{F}$) and the picofarad, abbreviated pF ($1 \text{pF} = 10^{-12} \text{F}$).

Capacitors can be fabricated onto integrated circuit (IC) chips. They are commonly used in conjunction with **transistors** in dynamic random access memory (DRAM). The capacitors help maintain the contents of memory.

Because of their tiny physical size, these components have low capacitance. They must be recharged thousands of times per second or the DRAM will lose its data.

Large capacitors are used in the power supplies of electronic equipment of all types, including computers and their peripherals. In these systems, the capacitors smooth out the rectified utility AC, providing pure, battery-like DC.

capacity on demand

Capacity on demand (COD) is a purchasing option that allows companies to receive equipment with more computer processing, storage, or other **capacity** than the company needs at the time of purchase, and have that extra capacity remain unused and unpaid for until the company actually requires it. Vendors are promoting capacity on demand as a cost-effective and time-saving alternative to more traditional methods of upgrading. With COD, a vendor might provide a company with a fully-configured 24-**processor** computer **server** but only charge the company for the number of processors they actually use. The vendor provides the additional capacity hoping that when the company expands and needs more capacity, they will not look around elsewhere but will simply take advantage of the extra capacity the vendor had already provided. In this scenario, the company would contact the vendor to have the extra processors activated, and the vendor would bill them accordingly.

Critics of COD compare the service with that of a hotel mini-bar, pointing out that the convenience of "instant gratification" can lead to poor capacity planning and ultimately, higher costs. The Meta Group has estimated that 80% of the world's 2,000 largest companies will provide customers with some kind of COD model by 2006. Leading COD vendors include IBM, Sun Microsystems, and Hewlett-Packard. Storage is currently the leading COD commodity.

CAPI

CAPI (Common Application Programming Interface) is an international standard **interface** that **applications** can use to communicate directly with **ISDN** equipment. Using CAPI, an application program can be written to initiate and terminate phone calls in computers equipped for ISDN. Computer telephony (CTI) applications can be written for ISDN users. Officially, CAPI is referred to as Common-ISDN-API and is embodied in ETS 300 838 ("Integrated Service Digital Network (ISDN); Harmonized Programmable Communication Interface (HPCI) for ISDN." ETS refers to standards from the European Telecommunication Standards Institute (ETSI). The standard is internationalized by recommendation T.200 "Programmable communication interface for terminal equipment connected to ISDN" from the International Telecommunications Union (ITU).

CAPI can be compared with the Intel-Microsoft “standard” programming interface, the Telephony Application Program Interface (**TAPI**). CAPI includes signaling and data exchange **protocols** not included in TAPI. TAPI services are also provided by CAPI and a TAPI application can be mapped to CAPI functions.

Because ISDN is widely used in Germany, the Netherlands, and Scandinavia, users there are accustomed to receiving a CAPI software program or **driver** along with their ISDN computer **card**. Not all CAPI driver versions support all functions. CAPI provides functions that are independent from physical signaling protocols that vary among different countries. CAPI supports these protocols: **HDLC**, HDLC inverted, **SDLC**, LAPD, X.75, Voice (PCM), Fax group 3 (T.30), V.110/V.120, and compression (**V.xx**).

carbon copy

In **e-mail**, a carbon copy (abbreviated “cc,” and sometimes “fcc” for “first carbon copy”) is a copy of a note sent to an addressee other than the main addressee. A blind carbon copy is a copy sent to an addressee that is not visible to the main and carbon copy addressees. For example, you may have a work colleague that acts as a back-up when you’re on vacation or not at work. You don’t necessarily want the people you correspond with to know that you have a back-up. So, to keep your back-up informed, you always send the back-up a blind carbon copy. The fact that a blind carbon copy was sent is not apparent to the main and carbon copy recipients.

The term is borrowed from the days of the mechanical and later the electronic typewriter (circa 1879-1979) when copies of typed sheets of paper were made by inserting a special sheet of inked paper called carbon paper into the typewriter. For two copies, you would insert carbon paper (sometimes just called a “carbon”) between the original being typed and each of the two sheets that would become the carbon copies.

card

A card (or *expansion card*, **board**, or **adapter**) is circuitry designed to provide expanded capability to a computer. It is provided on the surface of a standard-size rigid material (fiberboard or something similar) and then plugged into one of the computer’s expansion **slots** in its **motherboard** (or **backplane**). Cards may come in one of two sizes designed to match standard slot dimensions. A card can actually contain the capability within its circuitry (as a video card does) or it can control (through an extended connection) a device (such as a hard disk drive).

CardBus

CardBus is the trade name for an advanced **PC Card** (also known as PCMCIA card) specification. The technology is used primarily in notebook and portable computers. The CardBus card fits in a slot like a conventional PC card.

CardBus allows for all the functions that are possible with PC cards, but with these improvements:

- Direct Memory Access (**DMA**) is supported.
- A 32-bit path is used for data transfer.
- The operating speed is several times greater.
- CardBus works at lower battery voltage.

A CardBus slot, and the associated software, interrogates a card when the card is first inserted in the slot. If a PC card has been inserted, the computer uses it as if the slot were a conventional PCMCIA slot. If a CardBus card has been inserted, the computer reconfigures the slot to take advantage of the enhanced operating features. For CardBus to work, the **operating system** must support 32-bit data paths.

cardinal

Cardinal refers to a basic or primary value. Examples of cardinal numbers are 1, 7, 9, and 123. A cardinal rule is a rule that is basic or essential. Cardinal numbers can be contrasted with **ordinal** numbers.

cardinality

See also **integer**, **natural number**, **rational number**, and **real number**.

The term cardinality refers to the number of **cardinal** (basic) members in a **set**. Cardinality can be finite (a non-negative integer) or infinite. For example, the cardinality of the set of people in the United States is approximately 270,000,000; the cardinality of the set of integers is denumerably infinite.

In tables, the number of rows (or tuples) is called the cardinality. In practice, tables always have positive-integer cardinality. The reason for this is simple: tables with no rows, or with a negative number of rows, cannot exist. In theory, however, tables with denumerably infinite cardinality can exist. An example is a multiplication table of non-negative integers in which entries are implied for all possible values:

0	1	2	3	..
1	1	2	3	..
2	2	4	6	..
3	3	6	9	..
:	:	:	:	

The concept of cardinality is of interest to set theoreticians because it has been used to demonstrate that some infinite sets are larger than others. The cardinality of the set of real numbers is greater than the cardinality of the set of integers, even though both sets are infinite. The cardinality of the set of integers is called aleph-null or aleph-nought; the cardinality of the set of real numbers is called aleph-one.

One of the great mysteries of mathematics is contained in the question, “What is the cardinality of the set of points on a geometric line?” Generally it is presumed to be aleph-one;

the set of points on a line is thought to correspond one-to-one with the set of real numbers. This is by no means a trivial supposition, and has become known as the Continuum Hypothesis.

Carnivore

Carnivore is the Internet surveillance system developed by the U.S. Federal Bureau of Investigation (FBI), who developed it to monitor the electronic transmissions of criminal suspects. Critics, however, charge that Carnivore does not include appropriate safeguards to prevent misuse and might violate the constitutional rights of the individual.

Carnivore, a PC- or laptop-based application, is installed with an Internet service provider (ISP) to keep court-ordered tabs on a criminal suspect's e-mail and instant messages. The FBI says it cannot be enabled without help from the ISP. It works much like a commercial **sniffer** and other network diagnostic tools. The FBI says Carnivore has a unique ability to distinguish between communications that have been authorized for interception and those it does not have the right to search. For instance, Carnivore could be configured to intercept e-mail but not online shopping records.

Documents suggest that the FBI may have been working on a predecessor to Carnivore as early as 1996. But the FBI officially began the Carnivore project, under the name "Omnivore," in February 1997. It was proposed originally for a **Solaris** X86 computer. In June 1999, Omnivore was replaced by Carnivore running on a **Windows** NT-based system.

Carnivore's chief critic is the Electronic Privacy Information Center (EPIC), a public interest group dedicated to emerging civil liberties issues. The group sued and got the FBI to release background information on the system, although the Bureau refused to turn over Carnivore's source code. A private study conducted by the Illinois Institute of Technology Research Institute, which was commissioned by the U.S. Justice Department, found several shortcomings in Carnivore. For example, the system does not keep track of individual users, so any operator defaults to "administrator," leaving no audit trail. Also, the system lacks a feature that would require users to confirm that a court order was granted. The U.S. Congress is currently considering bills that would restrict the FBI's use of Carnivore.

Some security software vendors now claim to have developed alternatives to Carnivore. Carnivore could also lead to a rise in **encryption** software for Internet transactions, which would make such "sniffer" tools less effective.

carrier

1) In information technology, a carrier (or carrier signal) is a transmitted electromagnetic pulse or wave at a steady base frequency of alternation on which information can be imposed by increasing signal strength, varying the base frequency, varying the wave phase, or other means. This variation is called **modulation**. With the advent of laser transmission over **optical fiber** media, a carrier can also be a laser-generated light beam on which information is imposed.

Types of **analog** modulation of a carrier include amplitude modulation (AM), frequency modulation (FM), and phase modulation. Types of **digital** modulation include varieties of pulse code modulation (PCM), including pulse amplitude modulation (PAM), pulse duration modulation (PDM), and pulse position modulation (PPM).

Carrier detect (see **modem lights**) is a control signal between a **modem** and a computer that indicates that the modem detects a "live" carrier that can be used for sending and receiving information.

2) In the telecommunications industry, a carrier is a telephone or other company that sells or rents telecommunication transmission services. A local exchange carrier (LEC) is a local phone company and an inter-exchange carrier (IEC or IXC) carries long-distance calls.

Carrier Sense Multiple Access/Collision Detect

Carrier Sense Multiple Access/Collision Detect (CSMA/CD) is the **protocol** for carrier transmission access in **Ethernet** networks. On Ethernet, any device can try to send a **frame** at any time. Each device senses whether the line is idle and therefore available to be used. If it is, the device begins to transmit its first frame. If another device has tried to send at the same time, a **collision** is said to occur and the frames are discarded. Each device then waits a random amount of time and retries until successful in getting its transmission sent.

CSMA/CD is specified in the IEEE 802.3 standard.

carrierless amplitude/phase modulation

cartridge

See "tape"

CAS

1) In computer **memory** technology, CAS (column address strobe) is a signal sent to a dynamic random access memory (**DRAM**) that tells it that an associated address is a column address. A data bit in DRAM is stored in a cell located by the intersection of a column address and a row address. A **RAS** (row address strobe) signal is used to validate the row address.

2) In telecommunications, CAS (channel associated signaling) is signaling (for example, in a **T-carrier system** line) in which control **signals**, such as those for synchronizing and bounding **frames**, are carried in the same **channels** along with voice and **data** signals. This arrangement is an alternative to CCS (common channel signaling) in which a group of voice-and-data channels share a separate channel that is used only for control signals.

cascading style sheet

A cascading style sheet (CSS) is a Web page derived from multiple sources with a defined order of precedence where the definitions of any style element conflict. The Cascading Style Sheet, level 1 (CSS1) recommendation from the World Wide Web Consortium (W3C), which is implemented in the latest versions of the Netscape and Microsoft Web browsers, specifies the possible style sheets or statements that may determine how a given element is presented in a Web page.

CSS gives more control over the appearance of a Web page to the page creator than to the browser designer or the viewer. With CSS, the sources of style definition for a given document element are in this order of precedence:

1. The STYLE attribute on an individual element tag.
2. The STYLE element that defines a specific style sheet containing style declarations or a LINK element that links to a separate document containing the STYLE element. In a Web page, the STYLE element is placed between the TITLE statement and the BODY statement.
3. An imported style sheet, using the CSS @import notation to automatically import and merge an external style sheet with the current style sheet.
4. Style attributes specified by the viewer to the browser.
5. The default style sheet assumed by the browser.

In general, the Web page creator's style sheet takes precedence, but it's recommended that browsers provide ways for the viewer to override the style attributes in some respects. Since it's likely that different browsers will choose to implement CSS1 somewhat differently, the Web page creator must test the page with different browsers.

Cascading Style Sheet, level 1

CSS1 (Cascading Style Sheet, level 1) is the recommendation from the World Wide Web Consortium (W3C) for a standard **cascading style sheet** specification.

A cascading style sheet (CSS) is a **style sheet** derived from multiple sources with a defined order of precedence where the definitions of a style element conflict. CSS1 describes the recommended approach for Web page designers and browser developers to adhere to.

CASE

CASE (computer-aided software engineering) is the use of a computer-assisted method to organize and control the development of software, especially on large, complex projects involving many software components and people. Using CASE allows designers, code writers, testers, planners, and managers to share a common view of where a project stands at each stage of development. CASE helps ensure a disciplined, check-pointed process. A CASE tool may portray progress (or lack of it) graphically. It may also serve as a repository for or be linked to document and program libraries containing the project's business plans, design requirements, design specifications, detailed code specifications, the code units, test cases and results, and marketing and service plans.

CASE originated in the 1970s when computer companies were beginning to borrow ideas from the hardware manufacturing process and apply them to software development (which generally has been viewed as an insufficiently disciplined process). Some CASE tools supported the concepts of *structured programming* and similar organized development methods. More recently, CASE tools have had to encompass or accommodate visual programming tools and **object-oriented programming**. In corporations, a CASE tool may be part of a spectrum of processes designed to ensure quality in what is developed. (Many companies have their processes audited and certified as being in conformance with the ISO 9000 standard.)

Some of the benefits of CASE and similar approaches are that, by making the customer part of the process (through market analysis and focus groups, for example), a product is more likely to meet real-world requirements. Because the development process emphasizes testing and redesign, the cost of servicing a product over its lifetime can be reduced considerably. An organized approach to development encourages code and design reuse, reducing costs and improving quality. Finally, quality products tend to improve a corporation's image, providing a competitive advantage in the marketplace.

CAT 1 – CAT 2 – CAT 3 – CAT 4 – CAT 5 – CAT 5E – CAT 6 – CAT 7

See "Categories of twisted pair cabling systems"

catalog

In computing, a catalog is a directory of information about data sets, files, or a **database**. A catalog usually describes where a data set, file or database entity is located and may also include other information, such as the type of device on which each data set or file is stored.

categories of twisted pair cabling systems

ANSI/EIA (American National Standards Institute/Electronic Industries Association) Standard 568 is one of several standards that specify "categories" (the singular is commonly referred to as "CAT") of **twisted pair** cabling systems (wires, junctions, and connectors) in terms of the data rates that they can sustain. The specifications describe the cable material as well as the types of connectors and junction blocks to be used in order to conform to a category. These categories are:

Category	Maximum data rate	Usual application
CAT 1	Less than 1 Mbps	Analog voice (POTS) Integrated Services Digital Network Basic Rate Interface in ISDN Doorbell wiring
CAT 2	4 Mbps	Mainly used in the IBM Cabling System for Token Ring networks
CAT 3	16 Mbps	Voice and data on 10BASE-T Ethernet
CAT 4	20 Mbps	Used in 16 Mbps Token Ring Otherwise not used much
CAT 5	100 Mbps	100 Mbps TPDDI 155 Mbps ATM
CAT 5E	100 Mbps	100 Mbps TPDDI 155 Mbps ATM
CAT 6	200-250 MHz	Super-fast broadband applications

CAT 5 is currently under consideration to be incorporated into the **Gigabit Ethernet** specification for short distance wiring. While longer connections using Gigabit Ethernet use **optical fiber**, the goal is to leverage the CAT 5 twisted-pair wiring most organizations already have in place for connections out to the desktop.

The two most popular specifications are CAT 3 and CAT 5. While the two cables may look identical, CAT 3 is tested to a lower set of specifications and can cause transmission errors if pushed to faster speeds. CAT 3 cabling is **near-end crosstalk**-certified for only a 16 MHz signal, while CAT 5 cable must pass a 100 MHz test.

The CAT 6 specification was not yet formally approved by the EIA as of March 2001, although products are being offered that conform to a proposed specification. A CAT 7 specification is reportedly being considered.

cathode ray tube

A cathode ray tube (CRT) is a specialized **vacuum tube** in which images are produced when an electron beam strikes a phosphorescent surface. Most desktop computer displays make use of CRTs. The CRT in a computer display is similar to the "picture tube" in a television receiver.

A cathode ray tube consists of several basic components, as illustrated below. The electron gun generates a narrow beam of electrons. The anodes accelerate the electrons. Deflecting coils produce an **extremely low frequency** electromagnetic field that allows for constant adjustment of the direction of the electron beam. There are two sets of deflecting coils: horizontal and vertical. (In the illustration, only one set of coils is shown for simplicity.) The intensity of the beam can be varied. The electron beam produces a tiny, bright visible spot when it strikes the phosphor-coated screen.

To produce an image on the screen, complex signals are applied to the deflecting coils, and also to the apparatus that controls the intensity of the electron beam. This causes the spot to race across the screen from right to left, and from top to bottom, in a sequence of horizontal lines called the raster. As viewed from the front of the CRT, the spot moves in a pattern similar to the way your eyes move when you read a single-column page of text. But the scanning takes place at such a rapid rate that your eye sees a constant image over the entire screen.

The illustration shows only one electron gun. This is typical of a monochrome, or single-color, CRT. However, virtually all CRTs today render color images. These devices have three electron guns, one for the primary color red, one for the primary color green, and one for the primary color blue. The CRT thus produces three overlapping images: one in red (R), one in green (G), and one in blue (B). This is the so-called **RGB** color model.

In computer systems, there are several **display modes**, or sets of specifications according to which the CRT operates. The most common specification for CRT displays is known as SVGA (Super Video Graphics Array). Notebook computers typically use **liquid crystal displays**. The technology for these displays is much different than that for CRTs.

CATV

CATV (originally “community antenna television,” now often “community access television”) is more commonly known as “cable TV.” In addition to bringing television programs to those millions of people throughout the world who are connected to a community antenna, **cable TV** is an increasingly popular way to interact with the World Wide Web and other new forms of multimedia information and entertainment services.

CB

CCITT

The CCITT, now known as the ITU-T (for Telecommunication Standardization Sector of the International Telecommunications Union), is the primary international body for fostering cooperative standards for telecommunications equipment and systems. It is located in Geneva, Switzerland.

CCTV

CCTV (closed circuit television) is a television system in which signals are not publicly distributed; cameras are connected to television **monitors** in a limited area such as a store, an office building, or on a college campus. CCTV is commonly used in surveillance systems.

CD

See “compact disc”

CD burner

A CD burner is the informal name for a CD recorder, a device that can record data to a compact disc. CD-Recordable (**CD-R**) and CD-Rewritable (**CD-RW**) are the two most common types of drives that can write CDs, either once (in the case of CD-R) or repeatedly (in the case of CD-RW). In the recording process, the data is actually etched into the disc (burned) with a **laser**, as compared with non-recordable CDs. Audio CDs and **CD-ROMs** are pressed from copies of the original recordings (which are burned by lasers). Since the non-recordable CDs are manufactured in this manner, they can not be written, or rewritten in a desktop environment.

CD-Rs and CD-RWs, like all CDs, are made up of a polycarbonate substrate, a thin metal coating, and a protective outer layer. In a CD-R, a layer of organic polymer dye between the polycarbonate and metal layers serves as the recording medium. The composition of the dye is permanently transformed by exposure to a specific frequency of light. Some CD-Rs have an additional protective layer to make them less vulnerable to damage from scratches, since the data—unlike that on a regular CD—is closer to the label side of the disc. A pregrooved spiral track helps to guide the laser for recording data, which is encoded from the inside to the outside of the disc in a single continuous spiral. The laser creates marks in the dye layer that mimic the reflective properties of the *pits* and *lands* (lower and higher areas) of the traditional CD. The distinct differences in the way the areas reflect light register as **digital** data that is then unencoded for playback. With **packet writing** software and a compatible CD-R or CD-RW drive, it is possible to save data to a CD-R in the same way as one can save it to a floppy disk, although—since each part of the disk can only be written once—it is not possible to delete files and then reuse the space. The composition of the dye is permanently transformed by exposure to the laser.

In a CD-RW, the dye is replaced with an alloy that can change back and forth from a crystalline form when exposed to a particular light, through a technology called *optical phase change*. The patterns created are less distinct than those of other CD formats, requiring a more sensitive device for playback. Only drives designated as “MultiRead” are able to read CD-RW reliably. Similar to CD-R, the CD-RW’s polycarbonate substrate is preformed with a spiral groove to guide the laser. The alloy phase-change recording layer, which is commonly a mix of silver, indium, antimony and tellurium, is sandwiched between two dielectric layers that draw excess heat from the recording layer. After heating to one particular temperature, the alloy will become crystalline when it is cooled; after heating to a higher temperature it will become amorphous (won’t hold its shape) when it is cooled. By controlling the temperature of the laser, crystalline areas and non-crystalline areas are formed. The crystalline areas will reflect the laser, while the other areas will absorb it. The differences will register as binary data

that can be unencoded for playback. To erase or write over recorded data, the higher temperature laser is used, which results in the non-crystalline form, which can then be reformed by the lower temperature laser.

The first CD recorders were made available in 1988, but were not an option for the average home recorder because, with the requisite hardware and software, they cost upwards of \$100,000. At a weight of 600 pounds, the Meridian Data CD Professional was the first CD recorder. Today's CD recorders typically weigh a few pounds and can be bought for less than \$300.

CD Plus

See "enhanced CD"

CD recorder

See "CD burner"

CD-Bridge Disc

A CD-Bridge Disc (sometimes just called a *bridge disc*) is a compact disc (CD) format that includes extra information on a **CD-ROM XA** (extended architecture) track, so that the disc can be played on either a **CD-i** (interactive) player attached to a television, or a CD-ROM XA drive attached to a computer. A bridge disc with appropriate application software may also play on other XA-compatible devices, such as a **Photo CD** or Karaoke CD player. Video CD (**VCD**), Photo CD, and Karaoke CD are three bridge disc formats.

CD-Bridge Disc specifications are built on those from the **Yellow Book** extension, which defined CD-ROM XA, and the **Green Book**, which defined CD-i, and must conform to the complete requirements of both formats. The complete CD-Bridge Disc definition is described in the **White Book**, which was released by Sony, Philips, Matsushita, and JVC in 1993.

CD-Bridge Disk

See "CD-Bridge Disc"

CDF

See "Channel Definition Format"

CD-i

CD-i (Compact Disc—interactive) is the multimedia **CD** format specified in 1986 (in the **Green Book**). CD-i was specified as an entire system, comprising not just a disc and data format, but a hardware and software system, a variety of special **compression** methods for audio and visual data, and a method of interleaving audio, video, and text data. Developed as a user-friendly alternative to a PC, CD-i

players are easier to use, and have TV video output as well. Full screen motion video capabilities were added to the original specification later.

A CD-i player is a stand-alone system that includes a **CPU**, **memory**, and an integrated **operating system**. It can be connected to a TV set for displaying pictures and sound, or to a stereo system. The user interacts by positioning a cursor and selecting options, with a device such as a specialized remote control.

Although CD-i never realized broad commercial success, it is now used in education, training, and other professional applications.

CDMA

Also see **CDMA One**, **CDMA2000**, and **WCDMA**. Compare time-division multiplex (**TDM**) and frequency-division multiplex (**FDM**).

CDMA (code-division multiple access) refers to any of several protocols used in so-called second-generation (**2G**) and third-generation (**3G**) **wireless** communications. As the term implies, CDMA is a form of **multiplexing**, which allows numerous signals to occupy a single transmission **channel**, optimizing the use of available **bandwidth**. The technology is used in ultra-high-frequency (UHF) **cellular telephone** systems in the 800-MHz and 1.9-GHz bands.

CDMA employs analog-to-digital conversion (**ADC**) in combination with **spread spectrum** technology. Audio input is first digitized into binary elements. The frequency of the transmitted signal is then made to vary according to a defined pattern (code), so it can be intercepted only by a receiver whose frequency response is programmed with the same code, so it follows exactly along with the transmitter frequency. There are trillions of possible frequency-sequencing codes; this enhances privacy and makes cloning difficult.

The CDMA channel is nominally 1.23 MHz wide. CDMA networks use a scheme called **soft handoff**, which minimizes signal breakup as a handset passes from one cell to another. The combination of digital and spread-spectrum modes supports several times as many signals per unit bandwidth as analog modes. CDMA is compatible with other cellular technologies; this allows for nationwide **roaming**.

The original CDMA standard, also known as **CDMA One** and still common in cellular telephones in the U.S., offers a transmission speed of only up to 14.4 **Kbps** in its single channel form and up to 115 Kbps in an eight-channel form. **CDMA2000** and **wideband CDMA** deliver data many times faster.

CDMA One

Also see **CDMA**, **WCDMA**, and **CDMA2000**.

CDMA One, also written *cdmaOne*, refers to the original ITU IS-95 (**CDMA**) **wireless** interface protocol that was first standardized in 1993. It is considered a second-generation (2G) mobile wireless technology.

Today, there are two versions of IS-95, called IS-95A and IS-95B. The IS-95A protocol employs a 1.25-MHz carrier, operates in radio-frequency bands at either 800 MHz or 1.9 GHz, and supports data speeds of up to 14.4 Kbps. IS-95B can support data speeds of up to 115 kbps by bundling up to eight channels.

CDMA2000

Also see **CDMA**, **WCDMA**, and **CDMA One**.

CDMA2000, also known as IMT-CDMA Multi-Carrier or IS-136, is a code-division multiple access (**CDMA**) version of the IMT-2000 standard developed by the International Telecommunication Union (ITU). The CDMA2000 standard is third-generation (3-G) mobile **wireless** technology.

CDMA2000 can support mobile data communications at speeds ranging from 144 Kbps to 2 Mbps. Deployment is in the planning stages. Versions have been developed by Ericsson and Qualcomm.

CD-Magneto Optical

CD-Magneto Optical (CD-MO) is a **compact disc** format that uses magnetic fields for data storage. Defined by Philips and Sony in their 1990 *Recordable CD Standard*, informally known as the **Orange Book**, CD-MO discs can, at least theoretically, be rewritten an unlimited number of times.

CD-MO discs are constructed of an alloy of terbium ferrite and cobalt. The reading of an MO disc is based on the Kerr effect. In the Kerr effect, linear, polarized light is deflected when it is influenced by a magnetic field, and the plane of polarization is twisted. The MO method changes the magnetic characteristics of tiny areas on the disk's surface so that the reading **laser** beam is reflected differently on altered areas than on unaltered areas.

When writing to the disc, a laser beam is focused on an extremely small spot, and the alloy is heated to a specific temperature (called the *Curie point*) sufficient to cause the ferromagnetic properties of the aligned elementary particles to be lost. An electromagnet is positioned on the other side of the disc, changing the polarity of the particles, whose differences will be encoded as **binary** data for storage. Like other **optical media**, such as DVD and other CD formats, CD-MO is read by a laser beam, which makes it more reliable than a hard disk or a floppy disk. However, a strong magnetic field can corrupt the stored data.

CD-MO

See "CD-Magneto Optical"

CDO

See "Collaboration Data Objects"

CDPD

CDPD (Cellular Digital Packet Data) is a specification for supporting **wireless** access to the Internet and other public **packet-switched** networks. **Cellular telephone** and **modem** providers that offer CDPD support make it possible for mobile users to get access to the Internet at up to 19.2 Kbps. Because CDPD is an **open** specification that adheres to the layered structure of the Open Systems Interconnection (**OSI**) model, it has the ability to be extended in the future. CDPD supports both the Internet's **Internet Protocol** and the ISO Connectionless Network Protocol (**CLNP**).

CDPD also supports IP **multicast** (one-to-many) service. With multicast, a company can periodically broadcast company updates to sales and service people on the road or a news subscription service can transmit its issues as they are published. It will also support the next level of IP, **IPv6**.

For the mobile user, CDPD's support for packet-switching means that a persistent link isn't needed. The same broadcast channel can be shared among a number of users at the same time. The user's modem recognizes the packets intended for its user. As data such as e-mail arrives, it is forwarded immediately to the user without a circuit connection having to be established.

There is a **circuit-switched** version, called CS CDPD, that can be used where traffic is expected to be heavy enough to warrant a dedicated connection.

CD-R

CD-R (for *compact disc, recordable*) is a type of *write once, read many* (**WORM**) compact disc (**CD**) format that allows one-time recording on a disc. The CD-R (as well as the **CD-RW**) format was introduced by Philips and Sony in their 1988 specification document, the **Orange Book**. Prior to the release of the Orange Book, CDs had been read-only audio (CD-Digital Audio, described in the **Red Book**), to be played in CD players, and multimedia (**CD-ROM**), to be played in computers' CD-ROM drives. After the Orange Book, any user with a CD recorder drive could create their own CDs from their desktop computers.

Like regular CDs (all the various formats are based on the original Red Book CD-DA), CD-Rs are composed of a polycarbonate plastic substrate, a thin reflective metal coating, and a protective outer coating. However, in a CD-R, a layer of organic polymer dye between the polycarbonate and metal layers serves as the recording medium. The composition of the dye is permanently transformed by

exposure to a specific frequency of light. Some CD-Rs have an additional protective layer to make them less vulnerable to damage from scratches, since the data—unlike that on a regular CD—is closer to the label side of the disc. A pregrooved spiral track helps to guide the **laser** for recording data, which is encoded from the inside to the outside of the disk in a single continuous spiral. The laser creates marks in the dye layer that mimic the reflective properties of the *pits* and *lands* (lower and higher areas) of the traditional CD. The distinct differences in the way the areas reflect light register as **digital** data that is then unencoded for playback.

CD-R discs usually hold 74 minutes (650 **MB**) of data, although some can hold up to 80 minutes (700 MB). With **packet writing** software and a compatible CD-R or CD-RW drive, it is possible to save data to a CD-R in the same way that one can save it to a floppy disk, although—since each part of the disc can only be written once—it is not possible to delete files and then reuse the space. The rewriteable CDs, CD-RWs, use an alloy layer (instead of the dye layer) which can be transformed to and from a crystalline state repeatedly.

CD recorders (usually referred to as **CD burners**), were once much too expensive for the home user, but now are similar in price to CD-ROM drives. CD-Rs can be created in any CD-R or CD-RW drive.

CD-ROM

CD-ROM (Compact Disc—read-only-memory) is an adaptation of the **CD** that is designed to store computer data in the form of text and graphics, as well as hi-fi stereo sound. The original data format standard was defined by Philips and Sony in the 1983 **Yellow Book**. Other standards are used in conjunction with it to define directory and file structures, including **ISO 9660**, HFS (Hierarchical File System, for Macintosh computers), and Hybrid HFS-ISO. Format of the CD-ROM is the same as for audio CDs: A standard CD is 120 mm (4.75 inches) in diameter and 1.2 mm (0.05 inches) thick and is composed of a polycarbonate plastic substrate (underlayer—this is the main body of the disc), one or more thin reflective metal (usually aluminum) layers, and a lacquer coating.

The Yellow Book specifications were so general that there was some fear in the industry that multiple incompatible and proprietary formats would be created. In order to prevent such an occurrence, representatives from industry leaders met at the High Sierra Hotel in Lake Tahoe to collaborate on a common standard. Nicknamed the *High Sierra Format*, this version was later modified to become ISO 9660. Today, CD-ROMs are standardized and will work in any standard CD-ROM drive. CD-ROM drives can also read audio compact discs for music, although CD players cannot read CD-ROM discs.

CD-ROM Data Storage

Although the disc media and the drives of the CD and CD-ROM are, in principle, the same, there is a difference in the way data storage is organized. Two new sectors were defined, Mode 1 for storing computer data and Mode 2 for compressed audio or video/graphic data.

CD-ROM Mode 1

CD-ROM Mode 1 is the mode used for CD-ROMs that carry data and applications only. In order to access the thousands of data files that may be present on this type of CD, precise addressing is necessary. Data is laid out in nearly the same way as it is on audio disks: Data is stored in sectors (the smallest separately addressable block of information), which each hold 2,352 bytes of data, with an additional number of bytes used for error detection and correction, as well as control structures. For mode 1 CD-ROM data storage, the sectors are further broken down, and 2,048 used for the expected data, while the other 304 bytes are devoted to extra error detection and correction code, because CD-ROMs are not as fault tolerant as audio CDs. There are 75 sectors per second on the disk, which yields a disc capacity of 681,984,000 bytes (650MB) and a single speed transfer rate of 150 KBps, with higher rates for faster CD-ROM drives. Drive speed is expressed as multiples of the single speed transfer rate, as 2X, 4X, 6X, and so on. Most drives support **CD-ROM XA** (Extended Architecture) and Photo-CD (including multiple session discs).

CD-ROM Mode 2

CD-ROM Mode 2 is used for compressed audio/video information and uses only two layers of error detection and correction, the same as the CD-DA. Therefore, all 2,336 bytes of data behind the sync and header bytes are for user data. Although the sectors of CD-DA, CD-ROM Mode 1 and Mode 2 are the same size, the amount of data that can be stored varies considerably because of the use of sync and header bytes, error correction and detection. The Mode 2 format offers a flexible method for storing graphics and video. It allows different kinds of data to be mixed together, and became the basis for CD-ROM XA. Mode 2 can be read by normal CD-ROM drives, in conjunction with the appropriate drivers.

Data Encoding and Reading

The CD-ROM, like other CD adaptations, has data encoded in a spiral track beginning at the center and ending at the outermost edge of the disc. The spiral track holds approximately 650 MB of data. That's about 5.5 billion bits. The distance between two rows of pits, measured from the center of one track to the center of the next track is referred to as track pitch. The track pitch can range from 1.5 to 1.7 microns, but in most cases is 1.6 microns.

Constant Linear Velocity (CLV) is the principle by which data is read from a CD-ROM. This principal states that the read head must interact with the data track at a constant rate, whether it is accessing data from the inner or outermost portions of the disc. This is affected by varying the rotation speed of the disc, from 500 rpm at the center, to 200 rpm at the outside. In a music CD, data is read sequentially, so rotation speed is not an issue. The CD-ROM, on the other hand, must read in random patterns, which necessitates constantly shifting rotation speeds. Pauses in the read function are audible, and some of the faster drives can be quite noisy because of it.

CD-ROM XA

CD-ROM XA (Compact Disc – read-only-memory, extended architecture) is a modification of **CD-ROM** that defines two new types of sectors that enable it to read and display data, graphics, video, and audio at the same time. CD-ROM XA was developed jointly by Sony, Philips, and Microsoft, and its specifications were published in an extension to the **Yellow Book**.

CD-ROM XA (for eXtended Architecture) discs contain Mode 2 sectors (areas left free for extra data by the omission of error detection and correction code) and were designed to allow audio and other data to be interleaved and read simultaneously. Formerly, images had to be loaded before the audio tracks could be played. The CD-ROM XA specifications include 256 color modes, which are compatible with PC formats and **CD-I**, and Adaptive Differential Pulse Code Modulation (**ADPCM**) audio, which is also defined for CD-I. Photo CD, Video CD and **CD-EXTRA** have all subsequently been based on CD-ROM XA, although it has not survived as a separate technology.

CD-RW

CD-RW (for *compact disc, rewriteable*) is a compact disc (**CD**) format that allows repeated recording on a disc. The CD-RW format was introduced by Hewlett-Packard, Mitsubishi, Philips, Ricoh, and Sony, in a 1997 supplement to Philips and Sony's **Orange Book**. CD-RW is Orange Book III (**CD-MO** was I, while **CD-R** was II). Prior to the release of the Orange Book, CDs had been read-only audio (CD-Digital Audio, described fully in the **Red Book**), to be played in CD players, and multimedia (**CD-ROM**), to be played in computers' CD-ROM drives. After the Orange Book, any user with a CD Recorder drive could create their own CDs from their desktop computers. CD-RW drives can write both CD-R and CD-RW discs and can read any type of CD.

Like regular CDs (all the various formats are based on the original Red Book CD-DA), CD-Rs and CD-RWs are composed of a polycarbonate plastic substrate, a thin reflective metal coating, and a protective outer coating. CD-R is a *write once, read many* (**WORM**) format, in which a layer of organic polymer dye between the polycarbonate and metal layers serves as the recording medium. The

composition of the dye is permanently transformed by exposure to a specific frequency of light. In a CD-RW, the dye is replaced with an alloy that can change back and forth from a crystalline form when exposed to a particular light, through a technology called *optical phase change*. The patterns created are less distinct than those of other CD formats, requiring a more sensitive device for playback. Only drives designated as "MultiRead" are able to read CD-RW reliably.

Similar to CD-R, the CD-RW's polycarbonate substrate is preformed with a spiral groove to guide the **laser**. The alloy phase-change recording layer, which is commonly a mix of silver, indium, antimony, and tellurium, is sandwiched between two layers of **dielectric material** that draw excess heat from the recording layer. After heating to one particular temperature, the alloy will become crystalline when it is cooled; after heating to a higher temperature it will become amorphous (won't hold its shape) when it is cooled. By controlling the temperature of the laser, crystalline areas and non-crystalline areas are formed. The crystalline areas will reflect the laser, while the other areas will absorb it. The differences will register as **digital** data that can be unencoded for playback. To erase or write over recorded data, the higher temperature laser is used, which results in the non-crystalline form, which can then be reformed by the lower temperature laser.

CD-RW discs usually hold 74 minutes (650 **MB**) of data, although some can hold up to 80 minutes (700 MB) and, according to some reports, can be rewritten as many as 1000 times. With **packet writing** software and a compatible CD-RW drive, it is possible to save data to a CD-RW in the same way as one can save it to a floppy disk. CD recorders (usually referred to as **CD burners**), were once much too expensive for the home user, but now are similar in price to CD-ROM drives.

Celeron

Also see **Pentium**, **Xeon**, and **Pentium 3**.

Celeron is the low-end (and low cost) member of the family of **microprocessors** from Intel that is based on its P6 **architecture**. Although it is based on the same architecture as the Pentium II, it lacks some high-**performance** features of the Pentium II line. Celeron models later than the 300A include an **L1 and L2 cache** on the microchip, meaning that the cache is accessed at the same **clock speed** that the processor operates with. The Celeron L2 cache is smaller (128 **kilobytes**) than the Pentium II's (512 KB). However, because the Celeron L2 cache is on the processor chip and the Pentium II's is not, their effective L2 speeds are closely comparable. With clock speeds up to 466 **MHz**, Celeron processors are attractive to power users at first glance, but they should be compared to the Pentium II's computing power in order to get an idea of their useful application.

In ZDNet's CPUmark 99 **benchmark** tests, the Celeron processors compared favorably with Pentium II processors. Intel is marketing the processor as a chip for the basic PC.

They view it as providing performance good enough for home and business users doing word processing and Internet surfing. Power users and serious gamers may want to think about spending more for the Pentium II's top performance.

Celeron can be mounted in a **Slot 1 motherboard** or in a Socket 370 motherboard. Like Intel's other P6 microprocessors, the Celeron can be used for symmetric multiprocessing (SMP).

cell

1) In wireless telephony, a cell is the geographical area covered by a cellular telephone transmitter. The transmitter facility itself is called the *cell site*. The cell provided by a cell site can be from one mile to twenty miles in diameter, depending on terrain and transmission power. Several coordinated cell sites are called a cell system. When you sign up with a cellular telephone service provider, you generally are given access to their cell system, which is essentially local. When travelling out of the range of this cell system, the cell system can enable you to be transferred to a neighboring company's cell system without your being aware of it. This is called **roaming service**.

The cell sites in a system connect to a Mobile Telephone Switching Office (MTSO), which in turn connects to the standard landline telephone system.

2) In a battery power source, a cell is a single energy or charge-storing unit within a *pack* of cells that form the battery. Each cell has a voltage rating that is combined with the other cells' voltages to form the overall battery voltage rating.

Cell of Origin

Cell of Origin (COO) is a **mobile** positioning technique for finding a caller's **cell** (the basic geographical coverage unit of a **cellular telephone** system) location. It may be used by emergency services or commercial use. COO is the only positioning technique that is widely used in **wireless** networks and is used for Phase 1 of 911 service in the United States.

For COO positioning, the location of the base station is ascertained and considered to be the location of the caller. COO is a variable and not a very precise locator; depending on the number of base stations in the search area, accuracy may be as close as within one hundred meters of the target (in an urban area) or as far off as thirty kilometers away from the target where base stations are less densely concentrated. For this reason, when precision is important COO is often used in conjunction with some other technology, such as the Global Positioning System (GPS) or Time of Arrival (TOA).

Although COO positioning is not as precise as other methods, it offers unique advantages: It can very quickly identify the location (generally in about three seconds) and does not require equipment or network upgrades, which

makes it easily deployed to existing customer bases. The American National Standards Institute (ANSI), and the European Telecommunications Standards Institute (ETSI) recently formed the T1P1 subcommittee dedicated to creating standardization for positioning systems using TOA, Assisted GPS, and Enhanced Observed Time Difference in addition to COO.

cellspace

According to writer David S. Bennahum, cellspace is the kind of **cyberspace** you experience when equipped with a **cellular telephone** that can be connected to the Internet. Bennahum describes being able to receive e-mail through an air shaft in a subway tunnel, reading the mail on the subway, and sending the replies back after ascending to the street. Bennahum envisions new services that could be provided for mobile users, especially one that combined all the map, restaurant, airline reservation and timetable, rental car, and hotel information into a single site. Already, he notes, there are special services for travellers providing remote access to corporate **intranets**. Apart from services, Bennahum notes one characteristic common to many cellspace travellers: Because packet delivery is relatively slow with today's technology, services or users tend to dispense with the graphic images.

Bennahum's concept of cellspace is based on experience with his 3Com Palm Pilot, a Novatel Minstrel modem, and connection to a Cellular Digital Packet Data (CDPD) packet-switched network at 19 kilobits per second.

Cellular Digital Packet Data

See "CDPD"

cellular telephone

Cellular telephone is a type of short-wave **analog** or **digital** transmission in which a subscriber has a **wireless** connection from a mobile telephone to a relatively nearby transmitter. The transmitter's span of coverage is called a **cell**. Generally, cellular telephone service is available in urban areas and along major highways. As the cellular telephone user moves from one cell or area of coverage to another, the telephone is effectively passed on to the local cell transmitter.

A cellular telephone is not to be confused with a *cordless telephone* (which is simply a phone with a very short wireless connection to a local phone outlet). A newer service similar to cellular is **personal communications services** (PCS).

centimeter

The centimeter (abbreviation, cm) is a unit of displacement or length in the **cgs** (centimeter/gram/second) system of units. One centimeter is the distance traveled by a ray of

electromagnetic (EM) energy through a vacuum in $3.33564095 \times 10^{-11}$ of a second. It is equivalent to 0.01 **meter**. There are about 2.54 centimeters in one linear inch.

Power-of-10 **prefix multipliers** facilitate the derivation of other, often more convenient, distance units from the centimeter. One meter (m) is equal to 100 cm, one millimeter (mm) is equal to 0.1 cm, and one kilometer (km) is equal to 100,000 (10^5) cm. These units are found in nonscientific as well as scientific literature. Smaller units are the realm of the scientist and engineer. One micrometer (symbolized μm or μ), also called a micron, is equal to 0.0001 (10^{-4}) cm. One nanometer (nm) is equal to 10^{-7} cm. One Angström unit (symbolized Å) is equal to 10^{-8} cm, or 0.1 nm.

The centimeter and its kin are used to specify the **wavelengths** of EM fields, particularly at ultra-high and microwave radio frequencies. The so-called radio spectrum occupies an informally defined range of wavelengths from roughly 1 mm to several tens of kilometers. A 300-cm radio wave falls near the middle of the standard **FM** (frequency-modulation) broadcast band; a 1-cm radio wave corresponds to a frequency of approximately 30 gigahertz (**GHz**). The range of visible light wavelengths is from approximately 390 nm (violet) to 770 nm (red). The speed of **EM-field** propagation in a vacuum, to nine significant figures, is $2.99792458 \times 10^{10}$ centimeters per second.

Also see **displacement**, **meter**, **prefix multipliers**, and International System of Units (SI).

central office

In telephone communication in the U.S., a central office (CO) is an office in a locality to which subscriber home and business lines are connected on what is called a **local loop**. The central office has switching equipment that can switch calls locally or to long-distance carrier phone offices.

In other countries, the term *public exchange* is used.

Centronics parallel interface

The Centronics **parallel interface** is an older and still widely-used standard I/O interface for connecting **printers** and certain other devices to computers. The interface typically includes a somewhat cumbersome cable and a 36-**pin** male and female connector at the printer or other device. The cable plugs into a 25-pin parallel **port** on the computer. Data flows in one direction only, from the computer to the printer or other device. In addition to eight parallel data lines, other lines are used to read status information and send control signals. Centronics Corporation designed the original Centronics parallel interface for dot matrix printers. In 1981, IBM used this interface as an alternative to the slower one-bit-at-a-time **serial** interface.

When the Centronics parallel interface was first developed, the main peripheral was the printer. Since then, portable disk drives, **tape backup** drives, and **CD-ROM** players are among devices that have adopted the parallel interface.

These new uses caused manufacturers to look at new ways to make the Centronics parallel interface better. In 1991, Lexmark, IBM, Texas instruments, and others met to discuss a standard that would offer more speed and bi-directional communication. Their effort and the sponsorship of the **IEEE** resulted in the IEEE 1284 committee. The IEEE 1284 standard was approved for release in March 1994.

The IEEE 1284 standard specifies five modes of operation, each mode providing data transfer in either the forward direction (computer to peripheral), backward direction (peripheral to computer), or bi-directional (one direction at a time).

- **Compatibility mode** is the original Centronics parallel interface and intended for use with dot matrix printers and older laser printers. The compatibility mode can be combined with the nibble mode for bi-directional data transfer.
- **Nibble mode** allows data transfer back to the computer. The nibble mode uses the status lines to send 2 **nibbles** (4-bit units) of data to the computer in two data transfer cycles. This mode is best used with printers.
- **Byte mode** uses software **drivers** to disable the drivers that control the data lines in order for data to be sent from the printer to the computer. The data is sent at the same speed as when data is sent from the computer to the printer. One byte of data is transferred instead of the two data cycles required by the nibble mode.
- **ECP mode** (Enhanced Capability Port mode) is an advanced bi-directional mode for use with printers and **scanners**. It allows data **compression** for **images**, **FIFO** (first in, first out) for items in **queues**, and high-speed, bi-directional communication. Data transfer occurs at two to four megabytes per second. An advanced feature of **ECP** is **channel addressing**. This is used for multifunction devices such as printer/fax/modem devices. For example, if a printer/fax/modem device needs to print and send data over the modem at the same time, the channel address software driver of the ECP mode assigns a new channel to the modem so that both devices can work simultaneously.
- **EPP mode** (Enhanced Parallel Port mode) was designed by Intel, Xircom, and Zenith Data Systems to provide a high-performance parallel interface that could also be used with the standard interface. EPP mode was adopted as part of the IEEE 1284 standard. The EPP mode uses data cycles that transfer data between the computer and the peripheral and address cycles that assign address, channel, or command information. This allows data transfer speeds of 500 kilobytes to 2 megabytes per second, depending on the speed of the slowest interface. The EPP mode is bi-directional. It is suited for network adapters, data acquisition, portable hard drives, and other devices that need speed.

The computer must determine what the capabilities of the attached peripheral are and which mode to utilize. The concept developed to determine these factors is called negotiation. Negotiation is a sequence of events on the parallel port interface that determines which IEEE 1284 modes the device can handle. An older device will not respond to the negotiation sequence and compatibility mode is selected to operate that device. A newer device will respond to the negotiation sequence and a more advanced mode can be set.

CEO and others

CEO, CFO, CIO, and CTO are abbreviations that stand for: Chief Executive Officer, Chief Financial Officer, Chief Information Officer, and Chief Technology Officer. Modern corporations commonly use these terms to describe their top executives.

The CEO (Chief Executive Officer) is often but not always also the President of a company. The CEO reports to the Chairman of the Board and board members. The CEO is usually the most important spokesperson for the company, the person who is responsible for quarterly results, and the best paid member of the company.

The CFO (Chief Financial Officer) is sometimes also the company Treasurer and, in many companies, is seen as the second most important person in the company (since managing the quarterly results often depends on an understanding of how to keep the books).

The CIO (Chief Information Officer), a relative newcomer to the ranks of the top executives in a corporation, is responsible for a company's internal information systems, and, especially with the arrival of the Internet, sometimes in charge of the company's **e-business** infrastructure.

The CTO (Chief Technology Officer), an even newer arrival to the top executive ranks in many companies, is likely to be seen as the second or third most important person in any technology company. The CTO is responsible for research and development and possibly for new product plans.

CERN

CERN, the high-energy particle physics laboratory in Geneva, Switzerland, is where, in 1991, a researcher, Dr. Tim Berners-Lee, essentially invented the World Wide Web. Berners-Lee is credited with developing the idea of combining **hypertext** with the speed of today's electronic networks. Working with a small team, he developed the Hypertext Transfer Protocol (**HTTP**) on which the Web is based.

CERT

CERT (pronounced SUHRT), officially called the CERT Coordination Center, is the Internet's official emergency team. CERT (originally called the "Computer Emergency

Response Team") was formed by the Defense Advanced Research Projects Agency (**DARPA**) in November 1988 after the Internet was assaulted in the Internet worm incident. Today, CERT focuses on security breach and **denial-of-service** incidents, providing alerts and incident-handling and avoidance guidelines. CERT also conducts an ongoing public awareness campaign and engages in research aimed at improving security systems.

CERT is located at Carnegie-Mellon University in Pittsburgh where it is part of the Networked Systems Survivability program in the Software Engineering Institute, a federally funded research and development center.

certificate authority

A certificate authority (CA) is an authority in a network that issues and manages security credentials and **public keys** for message **encryption**. As part of a public key infrastructure (**PKI**), a CA checks with a registration authority (**RA**) to verify information provided by the requestor of a **digital certificate**. If the RA verifies the requestor's information, the CA can then issue a certificate.

Depending on the public key infrastructure implementation, the certificate includes the owner's public key, the expiration date of the certificate, the owner's name, and other information about the public key owner.

Certified Internet Webmaster

Certified Internet Webmaster (CIW) is a set of courses and exams that, when completed successfully, certifies an individual as capable in Web site development and server administration, including security and e-commerce. The CIW curriculum provides hands-on training for real-world Internet technologies that is independent of particular product vendors. A student may train at an instructor-led training site or train at home or at the office using conference calls, e-mail, and Web-based support. Examinations are administered by Sylvan Prometric, an independent testing body, at one of their testing centers. The Internet Certification Institute International (ICII) offers CIW certification worldwide and ProsoftTraining.Com offers the CIW certification program in the U.S. CIW certification is accredited by the Association of Internet Professionals and endorsed by the World Organization of Webmasters.

The first step toward certification is the CIW Foundations course. It provides basic knowledge of Internet technologies, network infrastructure, and Web page creation with the Hypertext Markup Language (**HTML**). All students must pass the exam at this level before taking other courses. Thereafter, the student may choose from one or more of the following courses:

- **CIW Site Designer:** This level teaches the student how to design, implement, and maintain a Web site with HTML, other authoring tools, and **script** languages, and how to use Web management and new media tools. This is a five-day course.
- **CIW Application Developer:** The student learns to build client and server-side Web applications. This course is divided into four sections totaling 10 days: **JavaScript Fundamentals** (2 days); **Visual Java Using Visual Café or Visual Age** (3 days); **Fundamentals of CGI Programming Using Perl** (2 days); and **Server-Side Scripting and Security** (3 days).
- **CIW Enterprise Developer:** An Enterprise Developer builds **n-tier** database and **legacy** solutions for Web applications. This course takes 10 days and is divided into four sections: **Java Programming Fundamentals** (5 days); **Enterprise Development with JFC** (Java Foundation Classes) and **Swing**, which is used to create **GUI** (graphical user interface) (2 days); **Enterprise Development with JDBC** (Java Database Connectivity) (1 day); and **Enterprise Development with CORBA** (Common Object Request Broker Architecture) and **Java** (2 days). A student needs a familiarity with Windows NT and web server administration concepts and a working knowledge of C, Pascal or C++. A student must complete the Foundations and Application Developer courses before taking this course.
- **CIW Server Administrator:** This course teaches a student how to manage and tune corporate Internet and intranet infrastructures, monitor Web server systems, news and mail servers, and configure and deploy e-business servers. A student needs a working knowledge of Windows NT including installation and configuration. The course takes five days to complete and is divided into two sections: **Internet System Management** (2 days) and **Advanced Internet System Management** (3 days).
- **CIW Internetworking Professional:** An Internetworking Professional defines network architecture, identifies infrastructure components, and monitors and analyzes network performance. Basically, the Internetworking Professional is responsible for the design and management of enterprise **TCP/IP** networks, including troubleshooting when necessary. This course is divided into three parts totaling seven days: **TCP/IP Internetworking** (2 days); **Advanced TCP/IP Concepts and Practices** (3 days); and **Simple Network Management Protocol (SNMP) Network Management** (2 days).
- **CIW Security Professional:** The Security Professional implements security policies, identifies security threats, develops and provides countermeasures using firewall systems and attack-recognition technologies, and manages the **deployment** of security solutions. The course is divided into four sections each two days long:

Network Security and Firewalls; Windows NT Network Security; UNIX and TCP/IP Network Security; and Security Auditing, Attacks, and Threat Analysis. A student must successfully complete both the Foundations and Internetworking Professional courses before taking this course.

- **CIW E-Commerce Professional:** The student learns how to design and implement **e-commerce** Web sites, identify customer needs, monitor customer usage patterns, determine order processes and service after the sale and how to determine what e-business solutions increase sales. The student examines the relationships between cardholders, issuers, merchants, acquirers, payment gateways, and third parties using Secure Electronic Transactions (**SET**), cryptography standards, **certificate authority**, and services including VeriSign and **CyberCash**. This course is five days long divided into two parts: **E-commerce Concepts and Practices** (2 days) and **E-commerce Strategy and Solutions** (3 days).

CFB

See “ciphertext feedback”

CFML

CFML (ColdFusion Markup Language) is a Web **page markup** language that allows a **Web site** developer to create **pages** with variable information (text or graphics) that is filled in dynamically (**on the fly**) in response to variables such as user input. Along with the usual Hypertext Markup Language (**HTML**) tags that determine page layout and appearance, the page creator uses CFML **tags** to bring in content based on the results of a database **query** or user input. CFML is a proprietary language developed for use with **ColdFusion**, a product from Allaire.

CFML tags perform all server-side tasks (such as **database** queries) by condensing complex processes, that would normally require knowledge of programming languages such as Java or C++, into four basic tags: CFQUERY, which is used to submit a structured query language (**SQL**) request to the database; CFOUTPUT, which is used to display the result of a query; and CFTABLE or CFCOL, which are used to display a preformatted table containing the results of a set of queries. Files created with CFML are saved as ColdFusion **templates** and use a “.cfm” extension.

channel

1) In telecommunications in general, a channel is a separate path through which signals can flow.

2) In the public switched telephone network (PSTN), a channel is one of multiple transmission paths within a single link between network points. For example, the commonly used (in North America) T-carrier system line service provides 24 64 Kbps channels for digital data transmission.

3) In radio and television, a channel is a separate incoming signal or program source that a user can select.

4) In optical fiber transmission using dense wavelength-division multiplexing (DWDM), a channel is a separate wavelength of light within a combined, multiplexed light stream.

5) On the World Wide Web, a channel is a preselected Web site that can automatically send updated information for immediate display or viewing on request. See **push technology**.

6) In computer and Internet marketing, a channel is a "middleman" between a product creator and the marketplace. Value-added resellers (VAR) and retail store chains are examples of channels in this context.

7) Using **Internet Relay Chat**, a channel is a specific chat group.

8) In IBM **mainframe** systems, a channel is a high bandwidth connection between a processor and other processors, workstations, printers, and storage devices within a relatively close proximity. It's also called a *local connection* as opposed to a *remote* (or telecommunication) *connection*.

channel bank

A channel bank is a device at a telephone company **central office** (public exchange) that converts **analog** signals from home and business users into digital signals to be carried over higher-speed lines between the central office and other exchanges. The analog signal is converted into a digital signal that transmits at a rate of 64 thousand bits per second (Kbps). This 64 Kbps signal is a standard known as a **digital signal X** signal. The signal is **time-division multiplexed** with other DS0 signals on the same line. Usually, the digital information is put on each DS0 signal using pulse code modulation (PCM).

Channel Definition Format

The Channel Definition Format (CDF) is a **file format** from Microsoft that lets you create a file that defines a Web "channel," which is a preselected Web site or group of related Web sites. To use the channel, a user needs to have the Microsoft Internet Explorer 4 or later **browser**. The CDF file identifies the Web page and subpages that the user sees after selecting a channel on the browser. The file may also identify subpages that may be selected from the main channel page. A channel developer for a Web site puts the CDF file on the Web server. A user who clicks on a channel (for example, from the Internet Explorer channel menu bar) is actually specifying the **Uniform Resource Locator** or Internet file name of the Channel Definition File that defines the channel.

The Channel Definition Format is an application of Extensible Markup Language (XML) that Microsoft is proposing as a standard way to describe a Web site channel. In Internet Explorer 5, the channel user implementation has been changed. The *Channel Bar* that formerly appeared automatically when Windows was started has been removed. Channels are now accessed as a special folder in the Favorites menu.

channel extender

A channel extender is a device used with IBM's S/390 line of computers to increase the maximum communication distances between the S/390 **channel-connected mainframe** computers, or between an S/390 and **peripheral** devices such as workstations, printers, and storage devices. As a rule, optical fiber channel connections transmit over **multimode fiber**, which sends data over multiple paths within the fiber for distances less than two miles. Channel extenders transmit over **single mode fiber**, which sends data over a single path for distances of up to—and sometimes greater than—eighteen miles. Because the channel extender increases the distance of possible connections, a channel-connected network may be able to operate with fewer S/390 computers.

CHAP

See “CHAP”

character

1) In information technology, a character is a printable symbol having phonetic or pictographic meaning and usually forming part of a word of **text**, depicting a numeral, or expressing grammatical punctuation. In information technology today, a character is generally one of a limited number of symbols, including the letters of a particular language’s alphabet, the numerals in the decimal number system, and certain special symbols such as the ampersand (&) and “**at sign**” (@).

Several standards of computer encoding have been developed for characters. The most commonly used in personal computers is **ASCII**. IBM mainframe systems use **EBCDIC**. A new standard, **Unicode**, is supported by later Windows systems.

2) A distinction is sometimes made between a character and a **glyph**. In this distinction, a character can be distinguished from other characters in terms of meaning and sound—a glyph is the graphic image used to portray the character. In different implementations, a character can have more than one possible glyph, and a glyph can represent more than one possible character.

characters per inch

See “CPI”

charge quantity

Charge quantity is an expression of the extent to which an object is electrically charged. It is also an expression of the relative number of charge carriers in a given region or volume.

The force with which two electrically charged bodies attract or repel depends on the product of the charge quantities in both objects, and also on the distance between the charge centers of the objects. If the polarities are the same, the force is repulsive; if the polarities are opposite, the force is attractive. For any two charged bodies, the force decreases in proportion to the square of the distance between their charge centers, assuming the charges on the objects do not change.

The most common unit of charge quantity is the **coulomb** (symbolized C). This is the charge unit in the International System of Units (**SI**) and represents approximately 6.24×10^{18} unit electric charges. The **statcoulomb** (statC) is the **cgs** (centimeter/gram/second) unit of charge quantity, and represents approximately 2.082×10^9 unit electric charges. A unit electric charge is the charge quantity contained in a single **electron** or **proton**. By convention, electrons are assigned negative charge, and protons are assigned positive charge.

The tables below facilitate conversion among coulombs, statcoulombs, and unit electric charges.

Unit (and symbol)	To convert to coulombs, multiply by:	Conversely, multiply by:
statcoulomb (statC)	3.3356×10^{-10}	2.9980×10^9
unit charge	1.60×10^{-19}	6.24×10^{18}

Unit (and symbol)	To convert to statcoulombs, multiply by:	Conversely, multiply by:
coulomb (C)	2.9980×10^9	3.3356×10^{-10}
unit charge	4.803×10^{-10}	2.082×10^9

Also see **coulomb**, **statcoulomb**, **small-unit metric system**, and International System of Units (**SI**).

charge-coupled device

A charge-coupled device (CCD) is a light-sensitive **integrated circuit** that stores and displays the data for an image in such a way that each **pixel** (picture element) in the image is converted into an electrical charge the intensity of which is related to a color in the color spectrum. For a system supporting 65,535 colors, there will be a separate value for each color that can be stored and recovered. CCDs are now commonly included in digital still and video cameras. They are also used in astronomical telescopes, scanners, and **bar code** readers. The devices have also found use in **machine vision** for robots, in **optical character recognition** (OCR), in the processing of **satellite** photographs, and in the enhancement of **radar** images, especially in meteorology.

A CCD in a digital camera improves **resolution** compared with older technologies. Some digital cameras produce images having more than one million pixels, yet sell for under \$1,000. The term *megapixel* has been coined in reference to such cameras. Sometimes a camera with an image of 1,024 by 768 pixels is given the label “megapixel,” even though it technically falls short of the mark. Another asset of the CCD is its high degree of sensitivity. A good CCD can produce an image in extremely dim light, and its resolution does not deteriorate when the illumination intensity is low, as is the case with conventional cameras.

The CCD was invented in 1969 at Bell Labs, now part of Lucent Technologies, by George Smith and Willard Boyle.

Charles Babbage

If John von Neumann is the father of modern computing, then the English mathematician and inventor Charles Babbage can be considered its grandfather. Babbage designed, though never built, a **Difference Engine** and an **Analytical Engine**, the world’s first computing machines.

Babbage worked as a mathematician in Cambridge University where he received his MA in 1817 and later, like Newton, whose mathematical principles he espoused, occupied the Lucasian chair in mathematics. As a scientist, Babbage was obsessed with facts and statistics and lived in a rationalistic world where it was assumed that if all facts, past and present, could be known then all future events were determinable. His statistical publications include "Table of the Relative Frequency of the Causes of Breaking of Plate Glass Windows" and "Table of Constants of the Class Mammalia," the minutiae of which included the heart rate of the pig. Babbage founded the Statistical Society in 1834.

A prolific disseminator of ideas and an eclectic inventor, Babbage's varied range of inventions reflected the diversity of his interests. Fascinated by the railroad, which was invented in his native England in 1823, Babbage devised a standard rail gauge width as well as a cowcatcher (for the front of trains). He also recorded inventions related to lighthouse signalling, code breaking, and the postal system. He founded the British Association for the Advancement of Science and the (Royal) Astronomical Society.

Although remembered today primarily for his calculating engines, Babbage left a legacy in the fields of political theory (he was an ardent industrialist) and operations research (where his 1832 publication, "On the Economy of Manufactures," cataloged the manufacturing processes of the day).

Charles Babbage died in London on October 18, 1871.

chassis

A chassis (pronounced TCHA-see or SHA-see) is the physical frame or structure of an automobile, an airplane, a desktop computer, or other multi-component device. *Case* is very similar in meaning, but tends to connote the protective aspect of the frame rather than its structure. People tend to choose one term or the other. The rest of this definition uses *chassis* but applies as well to the term *case*. Both terms (and *casing*) are derived from the Vulgate Latin for *box*. The plural form is also *chassis*.

In a computer, the chassis houses the main electronic components, including the **motherboard** (with places to insert or replace microchips for the main and possibly specialized processors and random access memory (**RAM**) and places for adding optional adapters (for example, for audio or video capabilities). Typically, room is provided for a **hard disk** drive and a **CD-ROM** drive.

The IBM PC chassis for its XT computers set an early de facto standard for a chassis configuration (sometimes referred to as the **form factor**). The desktop computer has since evolved through the AT model, the mini-AT, and the small-footprint PC. A later development was the vertical or tower chassis configuration, designed to be placed under a desk. The outer dimensions of a chassis are said to form its **footprint**.

The term is not usually applied to mobile and notebook computers perhaps because the hardware components have to be more tightly integrated. Some communications devices such as terminal servers have a chassis especially designed to handle many combinations of hardware add-ons. Such a chassis is described as *modular*.

chat abbreviations

For the funny little faces made with keyboard characters, see **emoticon**.

Usage note: Chat abbreviations that describe emotions are typically typed within less-than and greater-than symbols (for example, <BG> for "big grin"). Chat abbreviations that represent shorthand for sentences or phrases, such as "BBL" for "Be back later" are not usually typed within these symbols. Since some of these phrases happen to denote emotions, this usage rule can easily be violated.

Abbreviation	Meaning
ADN	Any day now
AFAIK	As far as I know
AFK	Away from keyboard
ARE	Acronym-rich environment
A/S/L?	Age/sex/location?
B4N	Bye for now
BAK	Back at the keyboard
BBIAB	Be back in a bit
BBL	Be back later
BEG	Big evil grin
BFD	Big f***ing deal
BFN	Bye for now
BG	Big grin
BIOYIOP	Blow it out your I/O port
BL	Belly laughing
BOTEC	Back-of-the-envelope calculation
BRB	Be right back
BTA	But then again...
BTW	By the way
BWTHDIK	But what the heck do I know...?
CU	See you
CUL	See you later
CUL8ER	See you later
CYA	Cover your ass
CYO	See you online
DBA	Doing business as
DFLA	Disenhanced four-letter acronym (that is, a TLA)
DL	Dead link
DIKU	Do I know you?
DITYID	Did I tell you I'm distressed?
DQMOT	Don't quote me on this
EG	Evil grin

Abbreviation	Meaning	Abbreviation	Meaning
EMFBI	Excuse me for butting in	KWIM?	Know what I mean?
EOM	End of message	L8R	Later
EOT	End of thread (meaning: end of discussion)	LD	Later, dude
ETLA	Extended three-letter acronym (that is, an FLA)	LDR	Long-distance relationship
F2F	Face to face	LLTA	Lots and lots of thunderous applause
FAQ	Frequently-ask question(s)	LOL	Laughing out loud
FISH	First in, still here	LRF	Little Rubber Feet (the little pads on the bottom of displays and other equipment)
FLA	Four-letter acronym	LTM	Laugh to myself
FMTYEWTK	Far more than you ever wanted to know	LTR	Long-term relationship
FOMCL	Falling off my chair laughing	LULAB	Love you like a brother
FUBAR	F**ed up beyond all repair or recognition	LULAS	Love you like a sister
FUD	Fear, Uncertainty, and Doubt	MorF	Male or female
FWIW	For what it's worth	MOSS	Member of the same sex
FYI	For your information	MOTOS	Member of the opposite sex
G	Grin	MUSM	Miss you so much
GA	Go ahead	NFG	No f****g good
GAL	Get a life	NFW	No feasible way or no f****g way
GDR	Grinning, ducking, and running	NIFOC	Naked in front of computer
GIWIST	Gee, I wish I'd said that	NP or N/P	No problem
GMTA	Great minds think alike	NRN	No response necessary
GOL	Giggling out loud	OIC	Oh, I see
GTRM	Going to read mail	OLL	Online love
HTH	Hope this helps	OTF	Off the floor
IAC	In any case	OTOH	On the other hand
IANAL	I am not a lawyer (but)	OTTOMH	Off the top of my head
IC	I see	PANS	Pretty awesome new stuff (as opposed to "POTS")
IHA	I hate acronyms	PCMCIA	People can't master computer industry acronyms
IIRC	If I recall/remember/recollect correctly	PDA	Public display of affection
ILU or ILY	I love you	PEBCAK	Problem exists between chair and keyboard
IM	Immediate message	PIBKAC	Problem is between keyboard and chair
IMHO	In my humble opinion	PITA	Pain in the ass
IMing	Chatting with someone online usually while doing other things such as playing trivia or other interactive game	PMFJIB	Pardon me for jumping in but...
IMNSHO	In my not so humble opinion	::POOF::	Goodbye (leaving the room)
IMO	In my opinion	POTS	Plain old telephone service
IOW	In other words	PU	That stinks!
IPN	I'm posting naked	RL	Real life (that is, when not chatting)
IRL	In real life (that is, when not chatting)	ROR	Raffing out roud (Engrish for "laughing out loud")
IYSWIM	If you see what I mean	ROTFL	Rolling on the floor laughing
JBOD	Just a bunch of disks (like redundant array of independent disks, etc.)		
JIC	Just in case		
JK	Just kidding		
KOTC	Kiss on the cheek		

#	Abbreviation	Meaning	Abbreviation	Meaning
A	ROTFLMAO	Rolling on the floor laughing my a** off	UW	You're welcome
B	ROTFLMAOWPIMP	Rolling on the floor laughing my a** off while peeing in my pants	VBG	Very big grin
C	ROTFLMBO	Rolling on the floor laughing my butt off	VBSEG	Very big s***-eating grin
D	RPG	Role-playing games	WDALYIC	Who died and left you in charge?
E	RSN	Real soon now	WFM	Works for me
F	RTFM	Read the f***ing manual	WIBNI	Wouldn't it be nice if
G	RYO	Roll your own (write your own program; derived from cigarettes rolled yourself with tobacco and paper)	WT?	What/who the ?
H	S4L	Spam for life (what you may get when you become someone's customer or client)	WTFO	What the F***! Over!
I	SHCOON	Shoot hot coffee out of nose	WTG	Way to go!
J	SEG	S***-eating grin	WTGP?	Want to go private?
K	SF	Surfer-friendly (low-graphics Web site)	WU?	What's up?
L	SNAFU	Situation normal, all f***ed up	WUF?	Where are you from?
M	SO	Significant other	WYSIWYG	What you see is what you get
N	SOL	Smiling out loud or sh*t out of luck	YGBSM	You gotta be s***tin' me!
O	SOMY	Sick of me yet?	YMMV	Your mileage may vary
P	STFW	Search the f****g Web		
Q	STW	Search the Web		
R	SWAG	Stupid wild-a** guess		
S	TAFN	That's all for now		
T	TANSTAAFL	There ain't no such thing as a free lunch		
U	TFH	Thread from hell (a discussion that just won't die and is often irrelevant to the purpose of the forum or group)		
V,W	TGIF	Thank God it's Friday		
X,Y,Z	TIA	Thanks in advance (used if you post a question and are expecting a helpful reply)		
	TLA	Three-letter acronym		
	TLK2UL8R	Talk to you later		
	TMI	Too much information		
	TOPCA	Til our paths cross again (early Celtic chat term)		
	TPTB	The powers that be		
	TTFN	Ta-Ta for now		
	TTT	Thought that, too (when someone types in what you were about to type)		
	TTYL	Talk to you later		
	TU	Thank you		
	UAPITA	You're a pain in the ass		

chat room

A chat room is a Web site, part of a Web site, or part of an online service such as America Online, that provides a venue for communities of users with a common interest to communicate in real time. Forums and discussion groups, in comparison, allow users to post messages but don't have the capacity for interactive messaging. Most chat rooms don't require users to have any special software; those that do, such as Internet Relay Chat (IRC) allow users to download it from the Internet.

Chat room users register for the chat room of their choice, choose a user name and password, and log into a particular room (most sites have multiple chat rooms). Inside the chat room, generally there is a list of the people currently online, who also are alerted that another person has entered the chat room. To chat, users type a message into a text box. The message is almost immediately visible in the larger communal message area and other users respond. Users can enter chat rooms and read messages without sending any, a practice known as **lurking**.

Because chat room messages are spontaneous and instantly visible, there is a potential for abuse, which may or may not be intentional. Site hosts typically post a frequently asked questions (FAQ) list to guide users to appropriate chat room behavior, such as introducing yourself when you enter a room, making it clear when you are directing a question or response to a specific user, and reporting disruptive users, for example. Disruptive users may verbally abuse other chatters, monopolize the conversation, or even just disable it by repeatedly typing the same word or phrase into the conversation, a practice (much frowned upon) known as *scrolling*.

Chat rooms can be found that focus on virtually any aspect of human endeavor or interest: There are current communities based on classic movies, Irish ancestry, baton

twirling, and psychic readings, for example. Various sites, such as Yahoo, provide a directory of chat sites. Others, such as MSN Web Communities, guide users through the steps required to create their own chat room.

chatterbot

A chatterbot is a program that attempts to simulate the conversation or “chatter” of a human being. Chatterbots such as “Eliza” and “Parry” were well-known early attempts at creating programs that could at least temporarily fool a real human being into thinking they were talking to another person. A chatterbot can be thought of as the spokesperson for an artificial intelligence (AI).

Chatterbots have been used in the online interactive games called Tinymuds. A single player may be able to interact with a chatterbot while awaiting other “live” players. At least one company is making a product that lets you build a chatterbot to handle sales-related or other questions on your Web site. And it is not difficult to imagine two chatterbots talking to each other and perhaps even exchanging information about each other so that their conversation could become more sophisticated. (To see how scary this could become, see **artificial intellect**.) And, of course, they would use some of the more common **chat abbreviations**.

chatting

For terms frequently used in online keyboard chatting, see **chat abbreviations**.

On the Internet, chatting is talking to other people who are using the Internet at the same time you are. Usually, this “talking” is the exchange of typed-in messages requiring one site as the repository for the messages (or “chat site”) and a group of users who take part from anywhere on the Internet. In some cases, a private chat can be arranged between two parties who meet initially in a group chat. Chats can be ongoing or scheduled for a particular time and duration. Most chats are focused on a particular topic of interest and some involve guest experts or famous people who “talk” to anyone joining the chat. (Transcripts of a chat can be archived for later reference.)

Chats are conducted on online services (especially America Online), by bulletin board services, and by Web sites. Several Web sites, notably Talk City, exist solely for the purpose of conducting chats. Some chat sites such as Worlds Chat allow participants to assume the role or appearance of an **avatar** in a simulated or *virtual reality* environment.

Talk City and many other chat sites use a protocol called **Internet Relay Chat**.

A chat can also be conducted using sound or sound and video, assuming you have the bandwidth access and the appropriate programming.

Cheapernet

See “Thinnet”

checksum

A checksum is a count of the number of bits in a transmission unit that is included with the unit so that the receiver can check to see whether the same number of bits arrived. If the counts match, it’s assumed that the complete transmission was received. Both **TCP** and **UDP** communication layers provide a checksum count and verification as one of their services.

Chief Information Officer

CIO (Chief Information Officer) is a job title commonly given to the person in an **enterprise** responsible for the information technology and computer systems that support enterprise goals. As information technology and systems have become more important, the CIO has come to be viewed in many organizations as a key contributor in formulating strategic goals. In many companies, the CIO reports directly to the Chief Executive Officer (CEO). In some companies, the CIO sits on the executive board. Typically, the CIO in a large enterprise delegates technical decisions to employees more familiar with details. Usually, a CIO proposes the information technology an enterprise will need to achieve its goals and then works within a budget to implement as much as possible of the plan.

Typically, a CIO is involved with analyzing and reworking existing business processes, with identifying and developing the capability to use new tools, with reshaping the enterprise’s physical infrastructure and network access, and with identifying and exploiting the enterprise’s knowledge resources. Many CIOs head the enterprise’s efforts to integrate the Internet and the World Wide Web into both its long-term strategy and its immediate business plans.

Chief Visionary Officer

Chief Visionary Officer (CVO) is a new title being used in corporations to differentiate the holder from other corporate executives including the Chief Executive Officer (CEO), the Chief Financial Officer (CFO), the Chief Information Officer (CIO), and the Chief Technology Officer (CTO). The CVO is expected to have a broad and comprehensive knowledge of all matters related to the business of the organization, as well as the vision required to steer its course into the future. The title is sometimes used to define a higher ranking position than that held by the CEO, and sometimes used to formalize a high-level advisory position. In some cases, the CVO is added to the CEO title (for CEO/CVO status), much in the same way that people with multiple university degrees list them after their names.

The first CVO was Tim Roberts, the young entrepreneurial founder of Broadband Investment Group. Roberts said he invented the title as a rank, superior to CEO, that served to recognize the visionary attributes needed to integrate a complex business with many diverse aspects. Roberts chose the title solely as definitive of his role in the organization, and didn't intend the designation to proliferate across the corporate world in the way that it has.

Corporations continue to invent new titles at an increasing rate—Chief Zoom Officer (CZO), Chief Smart Officer (CSO), and Chief Techie (CT) are a few of the more recent creations. Quinn Mills, a professor of business administration at Harvard Business School, claims that the proliferation of new titles is being used to attract and retain employees by offering them status—which is free—rather than money.

chip

"Chip" is short for microchip, the incredibly complex yet tiny modules that store computer **memory** or provide logic circuitry for microprocessors. Perhaps the best known chips are the **Pentium** microprocessors from Intel. The **PowerPC** microprocessor, developed by Apple, Motorola, and IBM, is used in Macintosh personal computers and some workstations. AMD and Cyrix also make popular microprocessor chips.

There are quite a few manufacturers of memory chips. Many special-purpose chips, known as application-specific integrated circuits, are being made today for automobiles, home appliances, telephones, and other devices.

A chip is manufactured from a **silicon** (or, in some special cases, a sapphire) wafer, which is first cut to size and then etched with circuits and electronic devices. The electronic devices use **complementary metal-oxide semiconductor** technology. The current stage of micro-integration is known as Very Large-Scale Integration (**VLSI**). A chip is also sometimes called an **IC** or *integrated circuit*.

chip art

See "microchip art"

chipset

A chipset is a group of **microchips** designed to work and sold as a unit in performing one or more related functions. A typical chipset is the Intel 430HX PCiSet for the **Pentium** microprocessor, a two-chip set that provides a **Peripheral Component Interconnect bus** controller and is designed for a business computer that "optimizes CPU, PCI and ISA transactions for faster, smoother multimedia performance in video conferencing, playback, and capture applications." This chipset includes support for the Universal Serial Bus (**USB**).

chmod

In a **UNIX-based operating system**, **chmod** (change mode) is a command used by a file owner or administrator to change the definition of access permissions to a file or set of files.

chorus

In audio production, chorus is one of the two standard audio effects defined by the Musical Instrument Digital Interface (**MIDI**). The other effect is **reverb** (reverberation). Chorus adds a swirling property to a sound that it is applied to, thickening the sound. Chorus is commonly used with instruments like the electric piano and guitar and with synthesizers. Most sound cards that have an onboard MIDI sound set contain both chorus and reverb.

A digital signal processing (**DSP**) **algorithm** that combines digital delays and at least one low-frequency **oscillator** (LFO) produces the chorus effect. The delays add a time offset and the LFOs vary the pitch. Varying the number of delays used in the design of the chorus DSP algorithm changes the quality of the chorusing effect. In addition, the number and speed of the LFOs used in the algorithm design also contribute to the overall effect. In general, the more individual delay lines and LFOs that are part of the DSP algorithm, the thicker and more complex the effect can be.

Here's how it works: An audio signal that is to be processed with chorus is first delayed by a small amount. (Typical delay times are small, in the range of 5 to 40 milliseconds.) This produces a doubling effect. Each delayed signal is then sent to the LFO. The LFO takes the delayed signal and moves its pitch up and down, changing the tuning from sharp to flat. The LFO usually runs at a slow speed; 1 to 5 oscillations per second are typical. The output of the delayed and pitch-altered signal is then mixed in with the original audio. This blending completes the chorusing effect.

CICS

CICS (Customer Information Control System) is an online transaction processing (**OLTP**) program from IBM that, together with the **COBOL** programming language, has formed over the past several decades the most common set of tools for building customer transaction applications in the world of large **enterprise mainframe** computing. A great number of the **legacy applications** still in use are COBOL/CICS applications. Using the application programming interface (**API**) provided by CICS, a programmer can write programs that communicate with online users and read from or write to customer and other records (orders, inventory figures, customer data, and so forth) in a database (usually referred to as "data sets") using CICS facilities rather than IBM's access methods directly. Like other transaction managers, CICS can ensure that transactions are completed and, if not, undo partly completed transactions so that the integrity of data records is maintained.

IBM markets or supports a CICS product for OS/390, UNIX, and Intel PC operating systems. Some of IBM's customers use IBM's Transaction Server to handle e-business transactions from Internet users and forward these to a mainframe server that accesses an existing CICS order and inventory database.

CIDR

CIDR (Classless Inter-Domain Routing) is a way to allocate and specify the Internet addresses used in inter-domain router more flexibly than with the original system of Internet Protocol (IP) address classes. As a result, the number of available Internet addresses has been greatly increased. CIDR is now the routing system used by virtually all gateway hosts on the Internet's backbone network. The Internet's regulating authorities now expect every Internet service provider (ISP) to use it for routing.

The original Internet Protocol defines IP addresses in four major classes of address structure, Classes A through D. Each of these classes allocates one portion of the 32-bit Internet address format to a network address and the remaining portion to the specific host machines within the network specified by the address. One of the most commonly used classes is (or was) Class B, which allocates space for up to 65,533 host addresses. A company who needed more than 254 host machines but far fewer than the 65,533 host addresses possible would essentially be "wasting" most of the block of addresses allocated. For this reason, the Internet was, until the arrival of CIDR, running out of address space much more quickly than necessary. CIDR effectively solved the problem by providing a new and more flexible way to specify network addresses in routers. (With a new version of the Internet Protocol—IPv6—a 128-bit address is possible, greatly expanding the number of possible addresses on the Internet. However, it will be some time before IPv6 is in widespread use.)

Using CIDR, each IP address has a *network prefix* that identifies either an aggregation of network gateways or an individual gateway. The length of the network prefix is also specified as part of the IP address and varies depending on the number of bits that are needed (rather than any arbitrary class assignment structure). A destination IP address or route that describes many possible destinations has a shorter prefix and is said to be less specific. A longer prefix describes a destination gateway more specifically. Routers are required to use the most specific or longest network prefix in the routing table when forwarding packets.

A CIDR network address looks like this:
192.30.250.00/18

The "192.30.250.00" is the network address itself and the "18" says that the first 18 bits are the network part of the address, leaving the last 14 bits for specific host addresses. CIDR lets one routing table entry represent an aggregation of networks that exist in the forward path that don't need to be specified on that particular gateway, much as the public

telephone system uses area codes to channel calls toward a certain part of the network. This aggregation of networks in a single address is sometimes referred to as a *supernet*.

CIDR is supported by The **Border Gateway Protocol**, the prevailing exterior (interdomain) gateway protocol. (The older exterior or interdomain gateway protocols, **Exterior Gateway Protocol** and **Routing Information Protocol**, do not support CIDR.) CIDR is also supported by the **OSPF** interior or intradomain gateway protocol.

CIFS

See "Common Internet File System"

cipher

A cipher (pronounced SAI-fuhr) is any method of encrypting text (concealing its readability and meaning). It is also sometimes used to refer to the encrypted text message itself although here the term **ciphertext** is preferred. Its origin is the Arabic *sifr*, meaning *empty* or *zero*. In addition to the cryptographic meaning, cipher also means (1) someone insignificant, and (2) a combination of symbolic letters as in an entwined weaving of letters for a monogram.

Some ciphers work by simply realigning the alphabet (for example, A is represented by F, B is represented by G, and so forth) or otherwise manipulating the text in some consistent pattern. However, almost all serious ciphers use both a **key** (a variable that is combined in some way with the unencrypted text) and an **algorithm** (a formula for combining the key with the text). A **block cipher** is one that breaks a message up into chunks and combines a key with each chunk (for example, 64-bits of text). A **stream cipher** is one that applies a key to each bit, one at a time. Most modern ciphers are block ciphers.

cipher block chaining

Also see **cryptography**.

Cipher block chaining (CBC) is a mode of operation for a **block cipher** (one in which a sequence of bits are encrypted as a single unit or block with a **cipher key** applied to the entire block). Cipher block chaining uses what is known as an initialization vector (IV) of a certain length. One of its key characteristics is that it uses a chaining mechanism that causes the **decryption** of a block of **ciphertext** to depend on all the preceding ciphertext blocks. As a result, the entire validity of all preceding blocks is contained in the immediately previous ciphertext block. A single bit error in a ciphertext block affects the decryption of all subsequent blocks. Rearrangement of the order of the ciphertext blocks causes decryption to become corrupted. Basically, in cipher block chaining, each plaintext block is XORed (see **XOR**) with the immediately previous ciphertext block, and then encrypted.

Identical ciphertext blocks can only result if the same plaintext block is encrypted using both the same key and the initialization vector, and if the ciphertext block order is not changed. It has the advantage over the **Electronic Code Book** mode in that the XOR'ing process hides plaintext patterns.

Ideally, the initialization vector should be different for any two messages encrypted with the same key. Though the initialization vector need not be secret, some applications may find this desirable.

ciphertext feedback

Also see **cryptography**.

Ciphertext feedback (CFB) is a mode of operation for a **block cipher**. In contrast to the **cipher block chaining** (CBC) mode, which encrypts a set number of bits of **plaintext** at a time, it is at times desirable to encrypt and transfer some plaintext values instantly one at a time, for which ciphertext feedback is a method. Like cipher block chaining, ciphertext feedback also makes use of an initialization vector (IV). CFB uses a block cipher as a component of a random number generator. In CFB mode, the previous ciphertext block is encrypted and the output is XORed (see **XOR**) with the current plaintext block to create the current ciphertext block. The XOR operation conceals plaintext patterns. Plaintext cannot be directly worked on unless there is retrieval of blocks from either the beginning or end of the ciphertext.

The **entropy** that results can be implemented as a **stream cipher**. In fact, CFB is primarily a mode to derive some characteristics of a stream cipher from a block cipher. In common with CBC mode, changing the IV to the same plaintext block results in different output. Though the IV need not be secret, some applications would see this desirable. Chaining dependencies are similar to CBC, in that reordering ciphertext block sequences alters decryption output, as decryption of one block depends on the decryption of the preceding blocks.

ciphertext

Ciphertext is encrypted **text**. **Plaintext** is what you have before **encryption**, and ciphertext is the encrypted result. The term **cipher** is sometimes used as a synonym for ciphertext, but it more properly means the method of encryption rather than the result.

CIR

See "committed information rate"

circuit

1) In electronics, a circuit is a path between two or more points along which an electrical current can be carried. (A *circuit breaker* is a device that interrupts the path when necessary to protect other devices attached to the circuit—for example, in case of a power surge.)

2) In telecommunications, a circuit is a discrete (specific) path between two or more points along which **signals** can be carried. Unless otherwise qualified, a circuit is a physical path, consisting of one or more wires and possibly intermediate switching points. A **network** is an arrangement of circuits. In a **dial-up** (switched) connection, a circuit is reserved for use by one user for the duration of the calling session. In a dedicated or leased line arrangement, a circuit is reserved in advance and can only be used the owner or renter of the circuit.

A **virtual circuit**, sometimes called a *logical circuit*, is a path between two or more points that seems like a fixed physical path, but actually is one path out of many possible physical paths that can be arranged. A permanent virtual circuit (**PVC**) is a virtual circuit that provides a guaranteed connection between two or more points when needed without having to reserve or commit to a specific physical path in advance. This allows many companies to share a common pool of circuits. This approach is used in a **frame relay** network and offers a committed set of resources to a telephone company customer at a lower price than if the customer leases their own circuits. A switched virtual circuit (**SVC**) is similar to a permanent virtual circuit, but allows users to dial in to the network of virtual circuits.

circuit-switched

Circuit-switched is a type of network in which a physical path is obtained for and dedicated to a single connection between two end-points in the network for the duration of the connection. Ordinary voice phone service is circuit-switched. The telephone company reserves a specific physical path to the number you are calling for the duration of your call. During that time, no one else can use the physical lines involved.

Circuit-switched is often contrasted with **packet-switched**. Some packet-switched networks such as the **X.25** network are able to have virtual circuit-switching. A virtual circuit-switched connection is a dedicated logical connection that allows sharing of the physical path among multiple virtual circuit connections.

CISC

The term "CISC" (complex instruction set computer or computing) refers to computers designed with a full set of computer instructions that were intended to provide needed capabilities in the most efficient way. Later, it was discovered that, by reducing the full set to only the most

frequently used instructions, the computer would get more work done in a shorter amount of time for most applications. Since this was called reduced instruction set computing (RISC), there was now a need to have something to call full-set instruction computers—thus, the term CISC.

The **PowerPC** microprocessor, used in IBM's RISC System/6000 workstation and Macintosh computers, is a RISC microprocessor. Intel's **Pentium** microprocessors are CISC microprocessors. RISC takes each of the longer, more complex instructions from a CISC design and reduces it to multiple instructions that are shorter and faster to process.

Citizen's Band Radio

Compare with **amateur radio**.

The Citizen's Band (CB) Radio Service, also known simply as CB, is a public, two-way personal radio service. There are several classifications of CB operation. The best-known form of CB is voice communications that became a fad in the 1970s. Mobile CB operation, especially in cars and trucks, remains popular. To a lesser extent, "CB'ers" engage in fixed operation from homes, and in portable communications using handheld transceivers.

Most CB operation takes place within a narrow band of frequencies near 27 MHz. There are 40 channels in this band. These channels are overcrowded. Congestion is worst during peaks in the 11-year sunspot cycle when the 27-MHz band supports worldwide communication known as "skip." Sunspot cycle peaks occurred in 1967-69, 1978-80, 1989-91, and 2000-2002. During the long intervals between these peaks, the normal range of operation on the 27-MHz band is rarely more than 20 miles.

Some CB operators illegally modify their equipment, or obtain illegally modified equipment, capable of higher transmitter output power and greater frequency coverage than is allowed by Federal Communications Commission (FCC) regulations. These operators use their equipment in an attempt to communicate over long distances, and/or to compete with other users of the service. This is called freebanding or bootlegging.

The CB Radio Service has proven useful in disaster situations, both small-scale (for example, for a stranded motorist) and large-scale (such as after a hurricane or during a flash flood). An organization of expert communicators known as the Radio Emergency Associated Communications Teams (REACT) provides communications support in emergency situations. Channel 9 (at 27.065 MHz) is monitored by members of REACT, and is recognized as the CB emergency channel in the U.S.

CIW

See "Certified Internet Webmaster"

class

In **object-oriented programming**, a class is a template definition of the **methods** and **variables** in a particular kind of **object**. Thus, an object is a specific instance of a class; it contains real values instead of variables.

The class is one of the defining ideas of object-oriented programming. Among the important ideas about classes are:

- A class can have subclasses that can inherit all or some of the characteristics of the class. In relation to each subclass, the class becomes the superclass.
- Subclasses can also define their own methods and variables that are not part of their superclass.
- The structure of a class and its subclasses is called the class hierarchy.

Class C2

Class C2 is a security rating established by the U.S. National Computer Security Center (NCSC) and granted to products that pass Department of Defense (DoD) Trusted Computer System Evaluation Criteria (TCSEC) tests. A C2 rating ensures the minimum allowable levels of confidence demanded for government agencies and offices and other organizations that process classified or secure information. TCSEC standards were established in the 1985 DoD document, *Department of Defense Trusted Computer System Evaluation Criteria*, known unofficially as the "Orange Book" (evaluation criteria for networks, the *Trusted Network Interpretation* is known as the "Red Book"). NCSC's objectives in publishing the document were: to provide DoD users with a means of ensuring the security of sensitive information; to provide manufacturers with guidelines to be followed; and to provide those involved in acquisitions with criteria for specifications.

According to TCSEC, system security is evaluated at one of four broad levels, ranging from class D to class A1, each level building on the previous one, with added security measures at each level and partial level. Class D is defined as *Minimum Security*; systems evaluated at this level have failed to meet higher level criteria. Class C1 is defined as *Discretionary Security Protection*; systems evaluated at this level meet security requirements by controlling user access to data. Class C2, defined as *Controlled Access Protection* adds to C1 requirements additional user accountability features, such as login procedures. Class B1 is defined as *Labeled Security Protection*; systems evaluated at this level also have a stated policy model, and specifically labeled data. Class B2, defined as *Structured Protection*, adds to B1 requirements a more explicit and formal security policy. Class B3, defined as *Security Domains*, adds stringent engineering and monitoring requirements and is highly secure. Class A1 is defined as *Verified Design*; systems evaluated at this level are functionally equivalent to B3 systems, but include more formal analysis of function to assure security.

Class of Service

Class of Service (CoS) is a way of managing traffic in a **network** by grouping similar types of traffic (for example, e-mail, streaming video, voice, large document file transfer) together and treating each type as a class with its own level of service priority. Unlike Quality of Service (**QoS**) traffic management, Class of Service technologies do not guarantee a level of service in terms of **bandwidth** and delivery time; they offer a “best-effort.” On the other hand, CoS technology is simpler to manage and more scalable as a network grows in structure and traffic volume. One can think of CoS as “coarsely-grained” traffic control and QoS as “finely-grained” traffic control.

There are three main CoS technologies:

- 802.1p Layer 2 Tagging
- Type of Service (ToS)
- Differentiated Services (**DiffServ**)

802.1p Layer 2 Tagging and ToS make use of three bits in the **Layer 2 packet header** that can be used to specify priority. Since three bits does not allow for much sophistication in managing traffic, a new protocol, Differentiated Services (DS or DiffServ), has been developed in draft form by an **IETF** Working Group. Differentiated Services uses a different approach to managing packets than simple priority labeling. It uses an indication of how a given packet is to be forwarded, known as the Per Hop Behavior (PHB). The PHB describes a particular service level in terms of bandwidth, **queueing theory**, and dropping (discarding the packet) decisions.

The Differentiated Services protocol exists as a set of related working documents from the Internet Engineering Task Force (**IETF**).

Classless Inter-Domain Routing

See “CIDR”

Claude Shannon

Claude Elwood Shannon, a mathematician born in Gaylord, Michigan (U.S.) in 1916, is credited with two important contributions to information technology: the application of **Boolean** theory to electronic switching, thus laying the groundwork for the digital computer, and developing the new field called *information theory*. It is difficult to overstate the impact which Claude Shannon has had on the 20th century and the way we live and work in it, yet he remains practically unknown to the general public. Shannon spent the bulk of his career, a span of over 30 years from 1941 to 1972, at Bell Labs where he worked as a mathematician dedicated to research.

While a graduate student at MIT in the late 1930s, Shannon worked for **Vannevar Bush** who was at that time building a mechanical computer, the Differential Analyser. Shannon

had the insight to apply the two-valued Boolean logic to electrical circuits (which could be in either of two states—on or off). This syncretism of two hitherto distinct fields earned Shannon his MS in 1937 and his doctorate in 1940.

Not content with laying the logical foundations of both the modern telephone switch and the digital computer, Shannon went on to invent the discipline of information theory and revolutionize the field of communications. He developed the concept of entropy in communication systems, the idea that information is based on uncertainty. This concept says that the more uncertainty in a communication channel, the more information that can be transmitted and vice versa. Shannon used mathematics to define the capacity of any communications channel to optimize the **signal-to-noise ratio**. He envisioned the possibility of error-free communications for telecommunications, the Internet, and satellite systems.

A Mathematical Theory Of Communication, published in the Bell Systems Technical Journal in 1948, outlines the principles of his information theory. Information Theory also has important ramifications for the field of **cryptology** as explained in his 1949 paper *Communication Theory of Secrecy Systems*—in a nutshell, the more entropy a cryptographic system has, the harder the resulting **encryption** is to break.

Shannon's varied retirement interests included inventing unicycles, motorized pogo sticks, and chess-playing robots as well as juggling—he developed an equation describing the relationship between the position of the balls and the action of the hands. Claude Shannon died on February 24, 2001.

CLC

See “customer life cycle”

clear channel

See “B8ZS”

CLEC

In the U.S., a CLEC (competitive local exchange carrier) is a company that competes with the already established local telephone business by providing its own network and switching. The term distinguishes new or potential competitors from established local exchange carriers (**LEC**) and arises from the **Telecommunications Act of 1996**, which was intended to promote competition among both long-distance and local phone service providers.

North American Telecom and Winstar Communications are examples of CLECs (which generally are listed as simply “local exchange carriers”).

click rate

In Web advertising, the click rate is the number of **clicks** on an ad on an HTML page as a percentage of the number of times that the ad was downloaded with a page. Thus, the click rate on a particular page with an ad would be 10% if one in ten people who downloaded the page clicked on the ad.

click stream

In Web advertising, a click stream is the sequence of clicks or pages requested as a visitor explores a Web site.

click

In Web advertising, a click is an instance of a user pressing down (clicking) on a mouse button in an ad space. The term *clickthrough* is also sometimes used. The **click rate** is the number of clicks on an ad as a percentage of the number of times that the ad was downloaded with a page.

clicks and mortar

Clicks and mortar (sometimes seen as *clicks-and-mortar*) is a term describing traditional *old economy* companies that are taking advantage of the Internet and the *new economy* it has introduced. The term derives from *bricks and mortar*, used in the context of the Web to describe traditional companies with physical (rather than Web site) locations. In the news media, the success of Internet companies like Amazon.com, the online bookstore, led to a comparison with traditional bricks and mortar businesses such as Barnes and Noble (which at some point added a competitive Web site and became an example of clicks and mortar).

As typically used in the media, a clicks and mortar company is one that has begun to exploit the Internet, not only in marketing and sales, but also in terms of its total business process. A clicks and mortar firm would be likely to take part in business-to-business (**B2B**) exchanges.

The term's origin is attributed to David Pottruck, CEO of Charles Schwab Corp, in a July 1999 speech at a conference sponsored by the Industry Standard. Pottruck is quoted as saying:

Schwab's vision has always been designed around customer needs and the company is engaged in constant reinvention to stay ahead of these powerful investors. Schwab believes that it is the combination of people and technology that investors want—a "high-tech and high-touch" approach. As such, Schwab is redefining the full-service business around the integration of "clicks and mortar."

clickthrough rate

In banner advertising on a Web site, the clickthrough rate (CTR) is the percentage of times that viewers of a Web page click on a given banner ad, causing a request for the advertiser's Web site to be transmitted to the viewer. For example, if two out of every 100 visitors to a Web page clicked on a given ad, that ad would be said to have a 2% clickthrough rate. (In most cases, a 2% clickthrough rate would be considered very successful, by the way. In many campaigns, especially as ads become familiar to users, the clickthrough rate is well below 1%.)

Many advertisers rate the success of a given ad placement on clickthrough rate alone. Other advertisers also place a value on the visitor's viewing of the ad, which is believed to create a desired company or product brand impression over time.

client

A client is the requesting program or user in a **client/server** relationship. For example, the user of a Web browser is effectively making client requests for pages from servers all over the Web. The browser itself is a client in its relationship with the computer that is getting and returning the requested HTML file. The computer handling the request and sending back the HTML file is a **server**.

client/server

Client/server describes the relationship between two computer programs in which one program, the client, makes a service request from another program, the server, which fulfills the request. Although the client/server idea can be used by programs within a single computer, it is a more important idea in a network. In a network, the client/server model provides a convenient way to interconnect programs that are distributed efficiently across different locations. Computer transactions using the client/server model are very common. For example, to check your bank account from your computer, a client program in your computer forwards your request to a server program at the bank. That program may in turn forward the request to its own client program that sends a request to a **database** server at another bank computer to retrieve your account balance. The balance is returned back to the bank data client, which in turn serves it back to the client in your personal computer, which displays the information for you.

The client/server model has become one of the central ideas of network computing. Most business applications being written today use the client/server model. So does the Internet's main program, **TCP/IP**. In marketing, the term has been used to distinguish distributed computing by smaller dispersed computers from the "monolithic" centralized computing of **mainframe** computers. But this distinction has

X,Y,Z

largely disappeared as mainframes and their applications have also turned to the client/server model and become part of network computing.

In the usual client/server model, one server, sometimes called a **daemon**, is activated and awaits client requests. Typically, multiple client programs share the services of a common server program. Both client programs and server programs are often part of a larger program or application. Relative to the Internet, your Web **browser** is a client program that requests services (the sending of Web pages or files) from a Web server (which technically is called a Hypertext Transport Protocol or **HTTP** server) in another computer somewhere on the Internet. Similarly, your computer with TCP/IP installed allows you to make client requests for files from File Transfer Protocol (**FTP**) servers in other computers on the Internet.

Other program relationship models included *master/slave*, with one program being in charge of all other programs, and **peer-to-peer**, with either of two programs able to initiate a transaction.

clip art

Clip art, frequently used in desktop publishing before the arrival of the Web, is "canned" artwork designed for use in publications or Web pages by artists or non-artists. The use of clip art can save artists time and make art both possible and economical for non-artists. Clip art includes both subject-related illustrations and visual elements such as horizontal lines, bullets, and text separators.

You can purchase clip art on specialized subjects from Adobe, Corel, and many smaller companies. You can purchase clip art and stock photography at Photodisc. You can also find much useful clip art for free personal use at many Web sites. For use on a commercial page, make sure you understand any restrictions. Some artwork requires written permission for use or the payment of a fee.

Many clip art sites now include **animated GIFs**.

cloaking

Also see **anonymous e-mail** and **remailer**.

Cloaking is the masking of the sender's name and address in an e-mail note or distribution. An individual or company that sends **spam** or, as they prefer to call it, "bulk e-mail" usually conceals their own e-mail address for various reasons, including the possibility that someone will swamp the originator's own e-mail server with retribitional spam.

clock cycle

In a computer, the clock cycle is the time between two adjacent pulses of the **oscillator** that sets the tempo of the computer processor. The number of these pulses per second is known as the **clock speed**, which is generally measured in **Mhz** (megahertz, or millions of pulses per second) and lately

even in **Ghz** (gigahertz, or billions of pulses per second). The clock speed is determined by a quartz-crystal circuit, similar to those used in radio communications equipment.

Some processors execute only one **instruction** per clock cycle. More advanced processors, described as **superscalar**, can perform more than one instruction per clock cycle. The latter type of processor gets more work done at a given clock speed than the former type. Similarly, a computer with a 32-bit bus will work faster at a given clock speed than a computer with a 16-bit bus. For these reasons, there is no simple, universal relation among clock speed, "bus speed," and millions of instructions per second (**MIPS**).

clock speed

In a computer, clock speed refers to the number of pulses per second generated by an **oscillator** that sets the tempo for the **processor**. Clock speed is usually measured in **MHz** (megahertz, or millions of pulses per second) or **GHz** (gigahertz, or billions of pulses per second). Today's personal computers run at a clock speed in the hundreds of megahertz and some exceed one gigahertz. The clock speed is determined by a quartz-crystal circuit, similar to those used in radio communications equipment.

Computer clock speed has been roughly doubling every year. The Intel 8088, common in computers around the year 1990, ran at 4.77 MHz. The 1 GHz mark was passed in the year 2000.

Clock speed is one measure of computer "power," but it is not always directly proportional to the performance level. If you double the speed of the clock, leaving all other hardware unchanged, you will not necessarily double the processing speed. The type of microprocessor, the **bus** architecture, and the nature of the instruction set all make a difference. In some applications, the amount of random access memory (**RAM**) is important, too.

Some processors execute only one **instruction** per clock pulse. More advanced processors can perform more than one instruction per clock pulse. The latter type of processor will work faster at a given clock speed than the former type. Similarly, a computer with a 32-bit bus will work faster at a given clock speed than a computer with a 16-bit bus. For these reasons, there is no simplistic, universal relation among clock speed, "bus speed," and millions of instructions per second (**MIPS**).

Excessive clock speed can be detrimental to the operation of a computer. As the clock speed in a computer rises without upgrades in any of the other components, a point will be reached beyond which a further increase in frequency will render the processor unstable. Some computer users deliberately increase the clock speed, hoping this alone will result in a proportional improvement in performance, and are disappointed when things don't work out that way.

clocks or cycles per instruction

See “CPI”

clone

A clone is an identical copy of something and is a term that first became familiar to the public from the biosciences. In the computer industry, the term became widely used in referring to imitations of the IBM PC by Compaq, Dell, and others. Clones of the PC allowed users to purchase a comparable personal computer at a much lower price than that offered by IBM and helped make PCs affordable for more people.

closed circuit television

Closed circuit television (CCTV) is a television system in which signals are not publicly distributed; cameras are connected to television **monitors** in a limited area such as a store, an office building, or on a college campus. CCTV is commonly used in surveillance systems.

cloud

In telecommunications, a cloud is the unpredictable part of any **network** through which data passes between two end points. Possibly the term originated from the clouds used in blackboard drawings or more formal illustrations to describe the nonspecifiable or uninteresting part of a network. Clouds exist because between any two points in a **packet-switched** network, the physical path on which a packet travels can vary from one packet to the next and, in a **circuit-switched** network, the specific circuit that is set up can vary from one connection to the next.

cluster

1) In personal computer storage technology, a cluster is the logical unit of file storage on a **hard disk**; it’s managed by the computer’s **operating system**. Any file stored on a hard disk takes up one or more clusters of storage. A file’s clusters can be scattered among different locations on the hard disk. The clusters associated with a file are kept track of in the hard disk’s file allocation table (**FAT**). When you read a file, the entire file is obtained for you and you aren’t aware of the clusters it is stored in.

Since a cluster is a logical rather than a physical unit (it’s not built into the hard disk itself), the size of a cluster can be varied. The maximum number of clusters on a hard disk depends on the size of a FAT table entry. Beginning with DOS 4.0, the FAT entries were 16 **bits** in length, allowing for a maximum of 65,536 clusters. Beginning with the Windows 95 **OSR2** service release, a 32-bit FAT entry is supported, allowing an entry to address enough clusters to support up to two **terabytes** of data (assuming the hard disk is that large!).

The tradeoff in cluster size is that even the smallest file (and even a directory itself) takes up the entire cluster. Thus, a 10-byte file will take up 2,048 bytes if that’s the cluster size. In fact, many operating systems set the cluster size default at 4,096 or 8,192 bytes. Until the **file allocation table** support in Windows 95 OSR2, the largest size hard disk that could be supported in a single **partition** was 512 **megabytes**. Larger hard disks could be divided into up to four partitions, each with a FAT capable of supporting 512 megabytes of clusters.

2) In information technology marketing and infrastructure terminology, a cluster is a group of terminals or workstations attached to a common control unit or server or a group of several servers that share work and may be able to back each other up if one server fails.

CMYK

Also see **hue, saturation, and brightness**.

CMYK is a scheme for combining primary pigments. The C stands for cyan (aqua), M stands for magenta (pink), Y is yellow, and K stands for black. The CMYK pigment model works like an “upside-down” version of the **RGB** (red, green, and blue) color model. Many paint and draw programs can make use of either the RGB or the CMYK model. The RGB scheme is used mainly for computer displays, while the CMYK model is used for printed color illustrations (hard copy).

There is a fundamental difference between color and pigment. Color represents energy *radiated* by a luminous object such as a cathode ray tube (**CRT**) or a light-emitting diode (**LED**). The *primary colors* are red (R), green (G), and blue (B). When you see a red area on a CRT, it looks red because it radiates a large amount of light in the red portion of the **electromagnetic radiation spectrum** (around 750 nanometers), and much less at other wavelength. Pigments, as opposed to colors, represent energy that is *not absorbed* by a substance such as ink or paint. The primary pigments are cyan (C), magenta (M), and yellow (Y). Sometimes black (K) is also considered a primary pigment, although black can be obtained by combining pure cyan, magenta, and yellow in equal and large amounts. When you see yellow ink on a

R
S
T
U
V,W
X,Y,Z

page, it looks yellow because it absorbs most energy at all visible wavelengths except in the yellow portion of the spectrum (around 600 nanometers), where most of the energy is reflected.

The primary pigments and the primary colors are mathematically related. Any two pure radiant primary colors (R, G, or B), when combined, produce radiation having the appearance of one of the pure non-black primary pigments (C, M, or Y). Any two pure non-black primary pigments, when mixed, produce a substance having the appearance of one of the pure primary colors.

The primary colors RGB, combined at 100-percent brilliance, produce white. The primary pigments CMY, combined at maximum concentration, produce black. Shades of gray result from equal (but not maximum) brilliances of R, G, and B, or from equal (but not maximum) concentrations of C, M, and Y. If you have a paint or draw program such as CorelDRAW! that employs both the RGB and the CMYK schemes, you can investigate these relationships by filling in regions with solid colors using one mode, and examining the equivalent in the other mode. After a while you will develop an intuitive sense of how these schemes work, how they resemble each other, and how they differ.

In general, the RGB mode should be used when preparing graphics intended mainly for viewing on computer displays. The CMYK mode should be used when creating illustrations for print media.

CNR

See "Communication and Networking Riser"

CO

See "central office"

coaxial antenna

A coaxial antenna is a variant of the **dipole antenna**, designed for use with an unbalanced **feed line**. One side of the antenna element consists of a hollow conducting tube through which a **coaxial cable** passes. The shield of the cable is connected to the end of the tube at the center of the radiating element. The center conductor of the cable is connected to the other half of the radiating element. The element can be oriented in any fashion, although it is usually vertical.

Coaxial antennas are used at frequencies above approximately 10 MHz, where the size is manageable. The design is especially popular among Class-D Citizens Band radio enthusiasts, who operate in a narrow band of frequencies near 27 MHz. Coaxial antennas are also used in short-range communications installations at VHF (very high frequencies) between 30 and 300 MHz.

If f is the frequency of operation in MHz, the overall length or height h of a coaxial antenna element in feet is given approximately by:

$$h = 460/f$$

For example, at 27 MHz:

$$h = 460/27 = 17 \text{ feet}$$

This is a manageable size for a self-supporting vertical antenna. The tubing, through which the feed line passes, forms the lower half of the antenna. It must be insulated from ground and from metallic supporting structures.

coaxial cable

Coaxial cable is the kind of copper cable used by **able TV** companies between the community antenna and user homes and businesses. Coaxial cable is sometimes used by telephone companies from their central office to the telephone poles near users. It is also widely installed for use in business and corporation **Ethernet** and other types of **local area network**.

Coaxial cable is called "coaxial" because it includes one physical **channel** that carries the signal surrounded (after a layer of insulation) by another concentric physical channel, both running along the same axis. The outer channel serves as a ground. Many of these cables or pairs of coaxial tubes can be placed in a single outer sheathing and, with repeaters, can carry information for a great distance.

Coaxial cable was invented in 1929 and first used commercially in 1941. AT&T established its first cross-continental coaxial transmission system in 1940. Depending on the carrier technology used and other factors, **twisted pair** copper wire and **optical fiber** are alternatives to coaxial cable.

COBOL

COBOL (Common Business Oriented Language) was the first widely-used high-level programming language for business applications. Many payroll, accounting, and other business application programs written in COBOL over the past 35 years are still in use and it is possible that there are more existing lines of programming code in COBOL than in any other programming language. While the language has been updated over the years, it is generally perceived as out-of-date and COBOL programs are generally viewed as **legacy** applications.

COBOL was an effort to make a programming language that was like natural English, easy to write and easier to read the code after you'd written it. The earliest versions of the language, COBOL-60 and -61, evolved to the COBOL-85 standard sponsored by the Conference on Data Systems Languages (CODASYL).

In years immediately preceding the year 2000, many COBOL programs required change to accommodate the new century. Programmers with COBOL skills were in demand by major corporations and contractors. A number of companies have updated COBOL and sell development tools that combine COBOL programming with relational databases and the Internet.

cobot

See "collaborative robot"

COD

See "capacity on demand"

code

1) In programming, code (noun) is a term used for both the statements written in a particular programming language—the **source code**, and a term for the source code after it has been processed by a **compiler** and made ready to run in the computer—the **object code**.

To code (verb) is to write programming statements—that is, to write the source code for a program.

2) In cryptography, code has both a specific technical meaning and a general meaning. In the technical sense, code is the substitution of one word or phrase by another word, number, or symbol for the purpose of concealing the original word or phrase. Basically, it's substitution at the word or phrase level. In industry, a developing product is sometimes given a code name to conceal its probable marketing name. Historically, military operations have often had a code name while in the preparation stage. In World War II, Germany's invasion of the Soviet Union was given the code name of Barbarossa. Code in this sense is sometimes confused with a **cipher**, which is substitution of symbols at the letter level. Modern cryptography is much more concerned with ciphers than with code in its limited technical meaning.

Code is often used generally to mean any kind of concealed writing, including ciphers. "Breaking the code" usually means the discovery of a way to read one or a series of encrypted messages without being given the key to decrypt them.

codec

1) In communications engineering, the term *codec* is used in reference to integrated circuits, or **chips** that perform data conversion. In this context, the term is an acronym for "coder/decoder." This type of codec combines **analog-to-digital conversion** and **digital-to-analog conversion** functions in a single chip. In personal and business computing applications, the most common use for such a device is in a **modem**.

2) The term *codec* is also an acronym that stands for "compression/decompression." A codec is an **algorithm**, or specialized computer program, that reduces the number of bytes consumed by large files and programs.

In order to minimize the amount of storage space required for a complicated file, such as a video, **compression** is used. Compression works by eliminating redundancies in data. Compression can be done for any kind of file, including text, programs, images, audio, video, and virtual reality (VR). Compression can reduce the size of a file by a factor of 100 or more in some cases. For example, a 15-megabyte video might be reduced to 150 kilobytes. The uncompressed file would be far too large to download from the Web in a reasonable length of time, but the compressed file could

T

U

V,W

X,Y,Z

usually be downloaded in a few seconds. For viewing, a *decompression* algorithm, which “undoes” the compression, would have to be used.

There are numerous standard codec schemes. Some are used mainly to minimize file transfer time, and are employed on the Internet. Others are intended to maximize the data that can be stored in a given amount of disk space, or on a CD-ROM.

Codecs are used in many popular Internet products, including QuickTime, Netmeeting, Cu-Seeme, and VDOphone.

coded orthogonal frequency division multiplexing

See “COFDM”

code-division multiple access

See “CDMA”

COFDM

COFDM is a **modulation** scheme that divides a single digital signal across 1,000 or more signal carriers simultaneously. The signals are sent at right angles to each other (hence, **orthogonal**) so they do not interfere with each other. COFDM is used predominately in Europe and is supported by the Digital Video Broadcasting (**DVB**) set of standards. In the U.S., the Advanced Television Standards Committee (**ATSC**) has chosen **8-VSB** (8-level Vestigial Sideband) as its equivalent modulation standard.

The main reason for Europe's decision to use COFDM is its ability to completely overcome multipath effects. When a signal is transmitted, it is met with obstructions such as canyons, buildings, and even people, which scatter the signal causing it to take two or more paths to reach its final destination, the television. The late arrival of the scattered portions of the signal cause ghost images. Multipath effects can occur simply by an individual walking into the room. For this very reason, some consumers in metropolitan areas or areas with rugged terrain opt for cable or satellite television instead of fighting their antennas for better reception. COFDM is resistant to multipath effects because it uses multiple carriers to transmit the same signal. Instead of the signal scattering when met with an obstacle, it flows around the obstacle like a river flows around a rock making it perfect for free DTV programming and for mobile television viewing. Problems with multipath effects were often cited in early evaluations of 8-VSB, although it is expected that devices such as internal antennas will overcome them.

In Europe, stations transmit the same signal 100 percent of the time across many borders using single frequency networks. A single frequency network is a network of several stations that broadcast the same signal simultaneously using multiple transmitters. This allows

television viewers to watch the same broadcast anywhere in Europe without interference. COFDM is ideal for single frequency networks.

COLD

COLD (Computer Output to Laser Disk) is a system for archiving data such as business records and reports to one or more optical disks in a compressed but easily retrievable format. COLD systems make it unnecessary to archive reports in printed form and are easier to work with than microfiche, an earlier solution. Vendors of COLD systems point out that more than one million paper pages can be stored on a single 5 1/4 inch optical disk. A COLD system consists of software and hardware. The software allows a user to send a document to the COLD system (much like sending it to be printed), organizes the documents for access, and compresses them for storage. The hardware consists of optical disk drives, which typically are mounted in a unit called a *jukebox*.

COLD software may offer the ability to do archiving automatically at scheduled times of day, to index documents in a variety of ways, and to periodically distribute the archive indexes.

COLD systems are used to archive accounting reports, credit reports, loan records, inventories, shipping and receiving documents, customer bills, lab reports, and many other kinds of records and reports. A COLD system is a form of **EDM** and is often used together with an **imaging** system.

cold site

See “hot site and cold site”

ColdFusion Markup Language

See “CFML”

ColdFusion

ColdFusion, developed by Allaire which has recently merged with Macromedia, is a popular and sophisticated set of products for building **Web sites** and serving **pages** to users. With ColdFusion, a company can build a content **database** using input **templates** and combine these with application programs to create a Web site in which pages are developed dynamically as they are served. ColdFusion consists of ColdFusion Studio, which is used to build a site, and ColdFusion Server, which serves the pages to users. ColdFusion Studio is described as “a complete integrated development environment (IDE)” and ColdFusion Server as “a **deployment platform**.”

The most valuable feature for many companies that use ColdFusion is the ability to build Web sites as “piece parts” that can be stored in a **database** and then reassembled for Web pages, e-mail newsletters, and other uses. ColdFusion provides a visual interface for building Web pages directly

or for building the “piece parts.” For example, a newspaper with a Web site can have a reporter enter a story, dateline, author, and other information, using a text entry form free of all Web page formatting and structure details or language **tags**. (The newspaper uses ColdFusion to design the forms and to define the database.) The content entered by the reporter is later gathered and formatted into a Web page when it is requested. The reporter is free from having to understand **HTML** and other details. ColdFusion is also a popular tool for building **e-commerce** sites.

ColdFusion has its own page **markup** language, called ColdFusion Markup Language (**CFML**). CFML encompasses the Web’s Hypertext Markup Language (**HTML**) and Extensible Markup Language (**XML**). A just-in-time (**JIT**) compiler turns the CFML into the pages that get served. Allaire emphasizes that their product set is **open** and “extensible.” Applications can access databases using Microsoft’s OLE DB, Open Database Connectivity (**ODBC**), or **drivers** that access Oracle and Sybase databases. ColdFusion can be coordinated with distributed applications that use Common Object Request Broker Architecture (**CORBA**) or Microsoft’s Distributed Component Object Model (**DCOM**) to interact with other network applications.

Allaire also says that ColdFusion is **scalable**, allowing both the size of a database and the number of users that can be served to grow. For large Web sites, multiple ColdFusion servers can be run together as a cluster.

Collaboration Data Objects

Collaboration Data Objects (CDO) is Microsoft’s technology for building **messaging** or collaboration **applications** or adding these capabilities to existing applications. Part of the Microsoft Exchange Server product, CDO has evolved from what Microsoft formerly called **Object Linking and Embedding** Messaging and, more recently, Active Messaging. Using **Active Server Page** (ASP) technology with CDO, a Web site builder can, for example, write a **script** that will exchange e-mail with users or with other Web sites, collaborate in discussions on other Web sites, or allow employees to schedule meetings with multiple recipients, review existing appointments, schedule new events, and so forth.

CDO is really an additional scripting interface to an existing Microsoft messaging model, the Messaging Application Programming Interface (**MAPI**). Collaborative Data Objects are made available through two CDO libraries. These libraries let you address programmable messaging objects (including folders, messages, recipient addresses, attachments, and other messaging components). These objects are extensions to the programmable objects, such as forms and controls, that are offered as part of Microsoft’s **Visual Basic** program development environment.

collaborative authoring

See “WebDAV”

collaborative robot

A **cobot** or “collaborative robot” is a robot designed to assist human beings as a guide or assistor in a specific task. A regular robot is designed to be programmed to work more or less autonomously. In one approach to cobot design, the cobot allows a human to perform certain operations successfully if they fit within the scope of the task and to steer the human on a correct path when the human begins to stray from or exceed the scope of the task.

collision

In an **Ethernet** network, a collision is the result of two devices on the same Ethernet network attempting to transmit data at exactly the same time. The network detects the “collision” of the two transmitted packets and discards them both. Collisions are a natural occurrence on Ethernets. Ethernet uses Carrier Sense Multiple Access/Collision Detect (**CSMA/CD**) as its method of allowing devices to “take turns” using the signal carrier line. When a device wants to transmit, it checks the signal level of the line to determine whether someone else is already using it. If it is already in use, the device waits and retries, perhaps in a few seconds. If it isn’t in use, the device transmits. However, two devices can transmit at the same time in which case a collision occurs and both devices detect it. Each device then waits a random amount of time and retries until successful in getting the transmission sent.

colocation

Colocation (sometimes spelled “co-location” or “collocation”) is the provision of space for a customer’s telecommunications equipment on the service provider’s premises. For example, a **Web site** owner could place the site’s own computer **servers** on the premises of the Internet service provider (**ISP**). Or an ISP could place its network **routers** on the premises of the company offering switching services with other ISPs. The alternative to colocation is to have the equipment and the **demarc** located at the customer’s premises.

Colocation is sometimes provided by companies that specialize in **Web site hosting**.

color thin film transistor

Color thin film transistor (CTFT) displays are **Thin Film Transistor** displays with color.

column address strobe

See “CAS”

com

On the Internet, “com” is one of the top-level **domain names** that can be used when choosing a domain name. It generally describes the entity owning the domain name as a commercial organization. Along with the second-level domain name (for example: “whatis” in *whatis.com*), the top-level domain name is required in Web and e-mail addresses.

The Internet Corporation for Assigned Names and Numbers (**ICANN**) has overall responsibility for domain names (as well as for **Internet Protocol** addresses and many other Internet parameters). Day-to-day responsibility is delegated to specific registrars, such as Network Solutions and a number of competing companies for .com, .org, .net, and .edu top-level domains.

Specific criteria are set forth for the use of the top-level domain name in RFC 1591—Domain Name System Structure and Delegation.

The top-level domain names administered by ICANN and its delegate agencies are: **com**, **edu**, **gov**, **int**, **mil**, **net**, and **org**. In addition to these, domain name applicants within the U.S. may also be able to register a name under a U.S. top-level domain name based on geography. See RFC 1480—The U.S. Domain and visit the U.S. Domain Registry for registration procedures.

Top-level domain names for countries other than the United States are administered by each country and are based on the ISO-3166 list of country codes.

COM+

COM+ is an extension of **Component Object Model (COM)**, Microsoft's strategic building block approach for developing application programs. COM+ is both an **object-oriented programming architecture** and a set of operating system services. It adds to COM a new set of system services for application **components** while they are running, such as notifying them of significant events or ensuring they are authorized to run. COM+ is intended to provide a model that makes it relatively easy to create business applications that work well with the Microsoft Microsoft Transaction Server (**MTS**) in a **Windows NT** or subsequent system. It is viewed as Microsoft's answer to the Sun Microsystems-IBM-Oracle approach known as Enterprise JavaBeans (**EJB**).

Among the services provided by COM+ are:

- An event registry that allows components to publish the possibility of an event and other components to subscribe to be notified when the event takes place. For example, when a sales transaction is completed, it could trigger an event that would allow other programs to be notified for subsequent processing.

- The interception of designated system requests for the purpose of ensuring security
- The **queues** of asynchronously received requests for a service

How COM+ Works Briefly

A “component” is a building block program that is self-describing. This means that it can be run with a mix of other components and each will be able to understand the capabilities and characteristics of the other components. Practically, this means that a new application can be built by reusing components already known to exist and without having to **compile** the application. It also makes it relatively easy to distribute different components of an application among different computers in a network. Microsoft's Distributed Component Object Model (**DCOM**) adds interfaces to do this.

In addition to its self-description, a component consists of one or more **classes** that describe objects and the methods or actions that can be performed on an **object**. A class (or *co*class in COM+ terminology) has properties described in an *interface* (or *co*interface). The class and its interface are language-neutral.

Associated with the class are one or more **methods** and fields that are implemented in a specific language such as **C++** or **Java** or a visual programming environment. When you **instantiate** a class, you create an object (something real that can be executed in the computer). Sometimes the term “class” is also used for the instantiated object (which can be confusing).

Using COM, objects (or classes) and their methods and associated data are compiled into binary executable **modules**, that are, in fact, files with a dynamic link library (**DLL**) or EXE file name suffix. A module can contain more than one class.

command interpreter

A command interpreter is the part of a computer **operating system** that understands and executes commands that are entered interactively by a human being or from a program. In some operating systems, the command interpreter is called the **shell**.

command line interface

A CLI (command line interface) is a user interface to a computer's **operating system** or an **application** in which the user responds to a visual prompt by typing in a command on a specified line, receives a response back from the system, and then enters another command, and so forth. The MS-DOS Prompt application in a Windows operating system is an example of the provision of a command line interface. Today, most users prefer the graphical user interface (**GUI**)

offered by Windows, **Mac OS**, **BeOS**, and others. Typically, most of today's **UNIX**-based systems offer both a command line interface and a graphical user interface.

command

In computers, a command is a specific order from a user to the computer's **operating system** or to an **application** to perform a service, such as "Show me all my files" or "Run this program for me." Operating systems such as **DOS** that do not have a graphical user interface (**GUI**) offer a simple *command line interface* in which you type the command on a designated line in a **display panel**. In a system such as Windows, a graphical user interface lets you implicitly enter commands by selecting objects or word selections and clicking your **mouse** button on them. (Windows does offer a command line interface for certain facilities if you select the "MS-DOS Prompt" under "Programs.")

The part of the operating system that handles commands is usually called a **command interpreter** or a **shell**. Some application programs, especially in **DOS**, provide a command mode for interfacing with the application from the display. In some operating systems, commands can be included in a list and presented to the system as a package to be **executed** in sequence, either immediately or at some specified time. Such a list is usually known as a **script**. One in which a time of execution is specified for each command is called a **CRON script**. In some systems, commands can be initiated from application programs as well as from a user interface.

Other approaches to giving commands to computers include **voice recognition**, **gesture recognition**, and even **thought recognition**.

comma-separated values file

In computers, a CSV (comma-separated values) file contains the values in a table as a series of **ASCII** text lines organized so that each column value is separated by a comma from the next column's value and each row starts a new line. Here's an example:

Doe,John,944-7077

Johnson,Mary,370-3920

Smith,Abigail,299-3958 (etc.)

A CSV file is a way to collect the data from any table so that it can be conveyed as input to another table-oriented application such as a application. Microsoft Excel, a leading spreadsheet or relational database application, can read CSV files. A CSV file is sometimes referred to as a **flat file**.

Commerce XML

Commerce XML (cXML) is a standard for the online exchange of business transaction information in common formats. It defines the structure of purchase orders, order acknowledgements, and other core e-business documents. cXML is a document type definition (DTD) based on XML

tags that defines fields for a specific type of document, like a purchase order. The XML structure enables an application program to easily extract data and deliver it to another application program.

Online catalog company Ariba Technologies led the cXML effort, but more than 40 companies collaborated on cXML, including Hewlett-Packard and Microsoft. The organizations hoped a common standard would reduce the cost of doing business online. The first version of cXML (version 0.91) appeared in May 1999.

commercial off-the-shelf

COTS (commercial off-the-shelf) describes ready-made products that can easily be obtained. The term is sometimes used in military procurement specifications.

commit

A commit is the final step in the successful completion of a previously started **database** change as part of handling a **transaction** in a computing system.

committed information rate

In **frame relay** networks, a committed information rate (CIR) is a **bandwidth** (expressed in bits per second) associated with a logical connection in a permanent virtual circuit (**PVC**). Frame relay networks are **digital** networks in which different logical connections share the same physical path and some logical connections are given higher bandwidths than others. For example, a connection conveying a high proportion of video signals (which require a high bandwidth) could be set up for certain workstations in a company (or on a larger network) and other connections requiring less bandwidth could be set up for all other workstations. Using statistical multiplexing, frame relay assemblers and disassemblers (**FRADs**), the devices that interconnect to the frame relay network, manage the logical connections so that, for example, those with the video signals (and higher CIRs) get more use of the paths. Because the CIR is defined in software, the network's mix of traffic bandwidths can be redefined in a relatively short amount of time.

Common Application Programming Interface

See "CAPI"

Common Business Oriented Language

See "COBOL"

common gateway interface

Also see **FastCGI**.

The common gateway interface (CGI) is a standard way for a Web server to pass a Web user's request to an application program and to receive data back to forward to the user. When the user requests a Web page (for example, by clicking on a highlighted word or entering a Web site address), the server sends back the requested page. However, when a user fills out a form on a Web page and sends it in, it usually needs to be processed by an application program. The Web server typically passes the form information to a small application program that processes the data and may send back a confirmation message. This method or convention for passing data back and forth between the server and the application is called the common gateway interface (CGI). It is part of the Web's Hypertext Transfer Protocol (HTTP).

If you are creating a Web site and want a CGI application to get control, you specify the name of the application in the uniform resource locator (URL) that you code in an HTML file. This URL can be specified as part of the FORMS tags if you are creating a form. For example, you might code:

```
<FORM METHOD=POST ACTION=http://www.mybiz.com/cgi-bin/formprog.pl>
```

and the server at "mybiz.com" would pass control to the CGI application called "formprog.pl" to record the entered data and return a confirmation message. (The ".pl" indicates a program written in **PERL** but other languages could have been used.)

The common gateway interface provides a consistent way for data to be passed from the user's request to the application program and back to the user. This means that the person who writes the application program can make sure it gets used no matter which operating system the server uses (PC, Macintosh, UNIX, OS/390, or others). It's simply a basic way for information to be passed from the Web server about your request to the application program and back again.

Because the interface is consistent, a programmer can write a CGI application in a number of different languages. The most popular languages for CGI applications are: C, C++, Java, and **PERL**.

An alternative to a CGI application is Microsoft's **Active Server Page (ASP)**, in which a **script** embedded in a Web page is executed at the server before the page is sent.

Common Internet File System

Common Internet File System (CIFS) is a proposed standard **protocol** that lets programs make requests for files and services on remote computers on the Internet. CIFS uses the **client/server** programming model. A **client** program makes a request of a **server** program (usually in another computer) for access to a file or to pass a message to a program that runs in the server computer. The server takes the requested

action and returns a response. CIFS is a public or **open** variation of the **Server Message Block Protocol** developed and used by Microsoft. The SMB Protocol is widely used in today's local area networks for server file access and printing. Like the SMB protocol, CIFS runs at a higher level than and uses the Internet's **TCP/IP** protocol. CIFS is viewed as a complement to the existing Internet application protocols such as the File Transfer Protocol (**FTP**) and the Hypertext Transfer Protocol (**HTTP**).

CIFS lets you:

- Get access to files that are local to the server and read and write to them.
- Share files with other clients using special locks.
- Restore connections automatically in case of network failure.
- Use **Unicode** file names. In general, CIFS gives the client user better control of files than the File Transfer Protocol. It provides a potentially more direct interface to server programs than currently available through the Web browser and its use of the HTTP protocol.

CIFS is an Open Group standard, X/Open CAE Specification C209, and has been proposed to the Internet Engineering Task Force (**IETF**) as an Internet application standard.

Common Management Information Protocol

Common Management Information Protocol (CMIP) is a network management protocol built on the Open Systems Interconnection (**OSI**) communication model. The related Common Management Information Services (CMIS) defines services for accessing information about network objects or devices, controlling them, and receiving status reports from them.

Common Object Request Broker Architecture

See "CORBA"

Common Programming Interface

See "CPI"

Communication and Networking Riser

Communication and Networking Riser (CNR), which was developed by Intel, is an open industry standard for a **scalable riser card**, which is a hardware device that plugs into a **motherboard** and holds chips for functions like modems and audio devices. The CNR architecture, and electrical, mechanical, and thermal requirements of the riser interface are defined in the specification.

The specification was developed for products used to implement low-cost local area network (**LAN**), modem, and audio subsystems and supports broadband, multichannel

audio, V.90 analog modem, Home PNA, and Ethernet-based networking, and can be expanded upon to meet the requirements of developing technologies, such as DSL. In addition to cost benefits, CNR has the capacity to minimize electrical noise interference, through physical separation of noise-sensitive elements from the motherboard's own communication systems.

competitive local exchange carrier

See "CLEC"

compiler

A compiler is a special program that processes statements written in a particular programming language and turns them into machine language or "code" that a computer's processor uses. Typically, a programmer writes language statements in a language such as Pascal or C one line at a time using an *editor*. The file that is created contains what are called the *source statements*. The programmer then runs the appropriate language compiler, specifying the name of the file that contains the source statements.

When executing (running), the compiler first parses (or analyzes) all of the language statements syntactically one after the other and then, in one or more successive stages or "passes," builds the output code, making sure that statements that refer to other statements are referred to correctly in the final code. Traditionally, the output of the compilation has been called *object code* or sometimes an *object module*. (Note that the term "object" here is not related to **object-oriented programming**.) The object code is **machine code** that the processor can process or "execute" one instruction at a time.

More recently, the Java programming language, a language used in **object-oriented programming**, has introduced the possibility of compiling output (called **bytecode**) that can run on any computer system platform for which a Java **virtual machine** or bytecode interpreter is provided to convert the bytecode into instructions that can be executed by the actual hardware processor. Using this virtual machine, the bytecode can optionally be recompiled at the execution platform by a **just-in-time compiler**.

Traditionally in some operating systems, an additional step was required after compilation—that of resolving the relative location of instructions and data when more than one object module was to be run at the same time and they cross-refered to each other's instruction sequences or data. This process was sometimes called *linkage editing* and the output known as a *load module*.

A compiler works with what are sometimes called 3GL and higher-level languages. An **assembler** works on programs written using a processor's assembler language.

complementary metal-oxide semiconductor

See "CMOS"

complex instruction set computer

See "CISC"

complex number

A complex number is a quantity of the form $v + iw$, where v and w are **real numbers**, and i represents the unit **imaginary numbers** equal to the positive square root of -1. The set **C** of all complex numbers corresponds one-to-one with the set $R \times R$ of all ordered pairs of real numbers. The set **C** also corresponds one-to-one with the points on a geometric plane.

The set of complex numbers is two-dimensional, and a coordinate plane is required to illustrate them graphically. This is in contrast to the real numbers, which are one-dimensional, and can be illustrated by a simple number line. The rectangular complex number plane is constructed by arranging the real numbers along the horizontal axis, and the imaginary numbers along the vertical axis. Each point in this plane can be assigned to a unique complex number, and each complex number can be assigned to a unique point in the plane.

Complex numbers are used in engineering, particularly in electronics. Real numbers are used to denote electrical **resistance**, imaginary numbers are used to denote **reactance**, and complex numbers are used to represent **impedance**.

component

1) In programming and engineering disciplines, a component is an identifiable part of a larger program or construction. Usually, a component provides a particular function or group of related functions. In programming design, a *system* is divided into *components* that in turn are made up of *modules*. *Component test* means testing all related modules that form a component as a group to make sure they work together.

2) In **object-oriented programming** and **distributed** object technology, a component is a reusable program building block that can be combined with other components in the same or other computers in a distributed network to form an application. Examples of a component include: a single button in a graphical user interface, a small interest calculator, an interface to a database manager. Components can be deployed on different servers in a network and communicate with each other for needed services. A component runs within a context called a **container**. Examples of containers include pages on a Web site, Web browsers, and word processors.

Sun Microsystems, whose **JavaBeans** application program interface defines how to create component, defines "a component model" as typically providing these major types of services:

- Component interface exposure and discovery. Thus, during application use, one component can interrogate another one to discover its characteristics and how to communicate with it. This allows different companies (possibly independent service providers) to create components that can interoperate with the components of other companies without either having to know in advance exactly which components it will be working with.
- Component properties. This allows a component to make its characteristics publicly visible to other components.
- Event handling. This allows one component to identify to one or more other components that an event (such as a user pressing a button) has occurred so that the component can respond to it. In Sun's example, a component that provided a button user interface for a finance application would "raise" an event when the button was pressed, resulting in a graph-calculating component gaining control, formulating a graph, and displaying it to the user.
- Persistence. This allows the state of components to be preserved for later user sessions.
- Application builder support. A central idea of components is that they will not only be easy and flexible for deploying in a distributed network, but that developers can easily create new components and see the properties of existing ones.

- Component packaging. Since a component may comprise several files, such as icons and other graphical files, Sun's component model includes a facility for packaging the files in a single file format that can be easily administered and distributed. (Sun calls their component package a JAR [Java Archive] file format.)

Component Object Model

Component Object Model (COM) is Microsoft's framework for developing and supporting program **component objects**. It is aimed at providing similar capabilities to those defined in the Common Object Request Broker Architecture (CORBA), a framework for the interoperation of distributed objects in a network that is supported by other major companies in the computer industry. Whereas Microsoft's **Object Linking and Embedding** provides services for the **compound document** that users see on their display, COM provides the underlying services of interface negotiation, life cycle management (determining when an object can be removed from a system), licensing, and event services (putting one object into service as the result of an event that has happened to another object).

COM includes **COM+**, Distributed Component Object Model (**DCOM**), and **ActiveX** interfaces and programming tools.

Component Object Model +

See "COM+"

compound document

In information technology, a compound document is an organized collection of user interfaces that form a single integrated perceptual environment. A compound document includes a data structure that contains different data types, such as text, audio files, and motion video files. A compound document is also an application environment containing program **objects** that can be interlinked and interacted with by a user.

Compound documents can be formed of information parts that originate from different sources and that are assembled **on the fly**. Microsoft's Internet Explorer **desktop** uses the compound document concept. Microsoft's **Object Linking and Embedding** is a framework for assembling and managing compound documents. *OpenDoc* is an alternative standard.

compression

Compression is the reduction in size of data in order to save space or transmission time. For data transmission, compression can be performed on just the data content or on the entire transmission unit (including *header* data) depending on a number of factors.

Content compression can be as simple as removing all extra space characters, inserting a single repeat character to indicate a string of repeated characters, and substituting smaller bit strings for frequently occurring characters. This kind of compression can reduce a text file to 50% of its original size. Compression is performed by a program that uses a formula or **algorithm** to determine how to compress or decompress data.

Graphic image file formats are usually designed to compress information as much as possible (since these can tend to become very large files).

When you send or receive information on the Internet, larger text files, either singly or with others as part of an **archive** file, may be transmitted in a zip, gzip, or other compressed format. **WinZip** is a popular Windows program that compresses files when it packages them in an archive.

compression artifact

A compression artifact is the fuzz or distortion in a **compressed** image or sequence of video images. When a photo is compressed into a **JPEG** format, some data is lost, which is why this type of compression is called **lossy compression**. The data that is lost is considered to be not necessary for the viewer to perceive or perhaps not perceivable in any case. In creating a JPEG, if you wish to have a smaller file size regardless of quality, then the result may introduce perceivable compression artifacts. However, if you wish to maintain the quality of the photo and have a larger file size, then the viewer may not notice any artifacts. Artifacts are more evident on a computer image than in a printed photograph.

A digital video file is also compressed and, depending on the amount of compression, may present artifacts. A digital video file has the same fuzzy edges and distortion of images as a still image (JPEG) file may have. The break up of the video into large digital **pixels** and jerkiness in the video stream are examples of compression artifacts.

computational reflection

Computational reflection (sometimes just called *reflection*) is a computer process involving self-awareness. Just as with humans, reflection depends on the capacity for independent reason, and particularly, reason about one's own processes. A reflective **program** has the ability to *metaprogram*: It can, itself, write programs. The capacity for reflection is one of the most important components of artificial intelligence (**AI**), and can be related to other aspects of AI such as **fuzzy logic** and **neural networks**.

When a reflective program operates, it does so in the same manner as a person. It takes variables, such as its own conditions, and contextual information into account. As an analogy, think of the operations involved in getting from your car to your house. If you see an obstacle in your path, you take in that information and adapt to it by either

stepping around or over the object, or picking it up. When you get to your door, if you find it locked, usually you don't stop and stand there, continue to turn the knob, or turn around and walk away; usually you take out your key and unlock the door. In the same way, a reflective program has the ability to think about what is happening and to alter itself to address the circumstances.

computer

A computer is a device that accepts **information** (in the form of **digital data**) and manipulates it for some result based on a **program** or sequence of instructions on how data is to be processed. Complex computers also include the means for storing data (including the program, which is also a form of data) for some necessary duration. A program may be invariable and built into the computer (and called *logic circuitry* as it is on **microprocessors**) or different programs may be provided to the computer (loaded into its storage and then started by an administrator or user). Today's computers have both kinds of programming.

Most histories of the modern computer begin with the **Analytical Engine** envisioned by **Charles Babbage** following the mathematical ideas of **George Boole**, the mathematician who first stated the principles of logic inherent in today's digital computer. Babbage's assistant and collaborator, **Ada Lovelace**, is said to have introduced the ideas of program loops and subroutines and is sometimes considered the first programmer. Apart from mechanical calculators, the first really useable computers began with the **vacuum tube**, accelerated with the invention of the **transistor**, which then became embedded in large numbers in integrated circuits, ultimately making possible the relatively low-cost personal computer.

Modern computers inherently follow the ideas of the stored program laid out by **John von Neumann** in 1945. Essentially, the program is read by the computer one instruction at a time, an operation is performed, and the computer then reads in the next instruction, and so on. Recently, computers and programs have been devised that allow multiple programs (and computers) to work on the same problem at the same time in parallel. With the advent of the Internet and higher **bandwidth** data transmission, programs and data that are part of the same overall project can be distributed over a network and embody the Sun Microsystems slogan: "The network is the computer."

Also see **analog computing**.

Computer Emergency Response Team

See "CERT"

computer operator

A computer operator is the person responsible for monitoring and controlling computer systems especially **mainframe** computer systems in a company or organization.

Responsibilities include troubleshooting software and hardware problems, monitoring **batch** processing, maintaining and improving system performance and online availability, maintaining all system and **application** documentation, and assisting personnel with computer problems. Other responsibilities depend on the employer but might include system backups, maintaining computer room equipment including printers and tape storage devices, and providing customer support.

A computer operator may often be asked to know or learn the main computers' operating systems, such as IBM's **OS/390** and its Job Entry Subsystem (**JES**), local area network operation, and applications used by an employer. A high school diploma is usually required. Most employers also require formal technical training or one to three years' experience. A computer operator must effectively interact and communicate with others, be able to work independently, have strong analytical skills, and be able to recognize and respond to problem situations.

concatenation

Concatenation (from Latin *concatenare*, to link together) is taking two or more separately located things and placing them side-by-side next to each other so that they can now be treated as one thing. In computer programming and data processing, two or more **character strings** are sometimes concatenated for the purpose of saving space or so that they can be addressed as a single item. (Of course, some way may be needed to know how to unconcatenate them later.)

A simple way to remember concatenation is to think of any word. What makes a word separate from other words is that all the letters are lined up together with no intervening spaces. That is, in a word, all letters are concatenated. Sometimes new words can be made by concatenating two existing words—for example, "airline" is a concatenation of the words "air" and "line" into a new word.

concentrator

As generally used, a concentrator is a device that acts as an efficient forwarder of data transmission signals. A remote access **hub** is sometimes referred to as a concentrator. The term **aggregator** is also frequently used with approximately the same meaning. A typical concentrator or remote access hub is a device that handles incoming dial-up calls for an

Internet (or other network) **point-of-presence** and performs other services. A concentrator or hub may be able to handle up to 100 dial-up modem calls, support a certain number of **ISDN** connections, and support **leased line** and **frame relay** traffic while also functioning as a **router**.

Concurrent Versions System

CVS also is an abbreviation for *Computer Vision Syndrome*.

Concurrent Versions System (CVS) is a program that lets a code developer save and retrieve different development versions of **source code**. It also lets a team of developers share control of different versions of files in a common repository of files. This kind of program is sometimes known as a *version control system*. CVS was created in the **UNIX operating system** environment and is available in both **Free Software Foundation** and commercial versions. It is a popular tool for programmers working on **Linux** and other UNIX-based systems.

CVS works not by keeping track of multiple copies of source code files, but by maintaining a single copy and a record of all the changes. When a developer specifies a particular version, CVS can reconstruct that version from the recorded changes. CVS is typically used to keep track of each developer's work individually in a separate working directory. When desired, the work of a team of developers can be merged in a common repository. Changes from individual team members can be added to the repository through a "commit" command.

CVS uses another program, Revision Control System (RCS), to do the actual revision management—that is, keeping the record of changes that goes with each source code file. The writers of the most popular CVS Frequently Asked Questions document are careful to emphasize that CVS is not a *build system*, a code configuration management system, or a substitute for other good development practices, but simply a way to control the versions of the pieces of a program as they are developed.

conditional access

Conditional access (CA) is a technology used to control access to digital television (**DTV**) services to authorized users by encrypting the transmitted programming. CA has been used for years for pay-TV services. There are numerous **ATSC** and **DVB**-compliant CA systems available for a broadcaster to choose from. The CA system provider provides the equipment and software to the broadcaster who then integrates the CA system into his equipment. CA is not designed solely for DTV. It can be used for digital radio broadcasts, digital data broadcasts, and non-broadcast information and interactive services. A CA system consists of several basic components:

- **Subscriber Management System (SMS):** The SMS is a subsystem of the CA system that manages the subscriber's information and requests entitlement management messages (EMM) from the Subscriber Authorization System (SAS). An EMM provides general information about the subscriber and the status of the subscription. The EMM is sent with the ECM. The ECM is a data unit that contains the **key** for decrypting the transmitted programs.
- **Subscriber Authorization System (SAS):** The SAS is a subsystem of the CA system that translates the information about the subscriber into an EMM at the request of the SMS. The SAS also ensures that the subscriber's security module receives the authorization needed to view the programs, and the SAS acts as a backup system in case of failure.
- **Security module:** The security module, usually in the form of a **smart card**, extracts the EMM and ECM necessary for decrypting the transmitted programs. The security module is either embedded within the **set-top box** or in a **PC card** that plugs into the set-top box.
- **Set-top box:** The set-top box houses the security module that gives authorization for decrypting the transmitted programs. The set-top box also converts the digital signal to an analogue signal so an older television can display the programs. There are two DVB protocols used by CA systems: SimulCrypt and MultiCrypt. SimulCrypt uses multiple set-top boxes, each using a different CA system, to authorize the programs for display. The different ECMs and EMMs required by each CA system are transmitted simultaneously. Each set-top box recognizes and uses the appropriate ECM and EMM needed for authorization. The ATSC standard uses SimulCrypt. MultiCrypt allows multiple CA systems to be used with one set-top box by using a PC card with an embedded smart card for each CA system used. Each card is then plugged into a slot in the set-top box. Each card recognizes the ECM and EMM needed for authorization.

A typical CA process involves three basic elements: the broadcast equipment, the set-top box, and the security module. The broadcast equipment generates the encrypted programs that are transmitted to the subscriber. When these are transmitted, the set-top box filters out the signals and passes them to the security module. The security module then authorizes these programs for decryption. The programs are then decrypted in **real time** and sent back to the set-top box for display.

conductance

Conductance is an expression of the ease with which electric **current** flows through a substance. In equations, conductance is symbolized by the uppercase letter *G*. The standard unit of conductance is the *siemens* (abbreviated *S*), formerly known as the *mho*.

When a current of one ampere (1 A) passes through a component across which a **voltage** of one volt (1 V) exists, then the conductance of that component is 1 S. The siemens is, in fact, equivalent to one ampere per volt. If *G* is the conductance of a component (in siemens), *I* is the current through the component (in amperes), and *E* is the voltage across the component (in volts), then:

$$G = I/E$$

In general, when the applied voltage is held constant, the current in a direct-current (**DC**) circuit is directly proportional to the conductance. If the conductance is doubled, the current is also doubled; if the conductance is cut to $1/10$ its initial value, the current also becomes $1/10$ as great. This rule also holds for most low-frequency alternating-current (**AC**) systems, such as household utility circuits. In some AC circuits, especially at high frequencies, the situation is more complex, because some components in these systems store and release energy, as well as dissipating or converting it.

Conductance is inversely related to **resistance**. If *R* is the resistance of a component or device (in ohms), then the conductance *G* (in siemens) is given by:

$$G = 1/R$$

CONFIG.SYS

CONFIG.SYS is a text file containing **DOS** (Disk Operating System) **commands** that tell the **operating system** how the computer is initially set up. More specifically, CONFIG.SYS commands specify memory device **drivers** and programs that control hardware devices; enable or disable system features; and set limits on system resources. CONFIG.SYS loads at startup before the **autoexec.bat** (automatic execute.batch program) file. Because CONFIG.SYS is a text file, it is editable in any text-editing program.

configuration management

Configuration management (CM) is the detailed recording and updating of information that describes an enterprise's computer systems and networks, including all hardware and software components. Such information typically includes the versions and updates that have been applied to installed software packages and the locations and network addresses of hardware devices. Special configuration management software is available. When a system needs a hardware or software upgrade, a computer technician can access the configuration management program and database to see what is currently installed. The technician can then make a more informed decision about the upgrade needed.

An advantage of a configuration management application is that the entire collection of systems can be reviewed to make sure any changes made to one system do not adversely affect any of the other systems

Configuration management is also used in software development, where it is called Unified Configuration Management (UCM). Using UCM, developers can keep track of the **source code**, documentation, problems, changes requested, and changes made.

connection

1) In telecommunication and computing in general, a connection is the successful completion of necessary arrangements so that two or more parties (for example, people or programs) can communicate at a long distance. In this usage, the term has a strong physical (hardware) connotation although logical (software) elements are usually involved as well.

A **dialup** (sometimes called a **switched**) connection is a telephonic arrangement that is set up only when needed, using shared, **circuit-switched** communication lines (as in "**plain old telephone service**"). A **dedicated** (sometimes called a **nonswitched**) connection is a continuous, always available connection (familiar to users of Digital Subscriber Line or **DSL** service). A **leased line** is a line rented from a telephone company that provides dedicated connection between two points (such as a headquarters office and a manufacturing plant).

2) In computer programming, a connection is the setting up of resources (such as computer memory and buffers) so that a particular object such as a **database** or **file** can be read or written to. Typically, a programmer encodes an OPEN or similar request to the operating system that ensures that system resources such as memory are set up, encodes READs and WRITES or similar requests, and then encodes a CLOSE when a connection is no longer needed so that the resources are returned to the system for other users.

A closely related term is **session**, which is sometime used to distinguish the ability to communicate for some duration in a logical sense. In this usage, the connection is regarded as the physical setup and the session is regarded as the logical setup. A session could be terminated and the connection maintained with the expectation of a new session later.

connectoid

A connectoid is a dial-up connection profile using the Microsoft Windows 95 or the **Windows 98 operating system**. The connection profiles allow a user to dial out (or really have the computer dial out) to a number of different Internet connection points such as Compuserve or a local Internet service provider (**ISP**).

Any user that connects to an Internet provider can decrease logon time by specifying only those services and **protocol** that are necessary in the Server Type settings for your connectoid.

contact port numbers

See "well-known port numbers"

container

1) In Sun Microsystems' **JavaBeans** component architecture and in Microsoft's **Component Object Model (COM)**, a container is an application program or subsystem in which the program building block known as a **component** is run. For example, a component—such as a button or other graphical user interface or a small calculator or database requestor—can be developed using JavaBeans that can run in Netscape containers such as browsers and in Microsoft containers such as Internet Explorer, Visual Basic, and Word.

2) In the Common Object Request Broker Architecture (**CORBA**) Interface Repository, a hierarchy for *metadata*, a Container is one of three *abstract superclasses* (along with IObject, and Contained).

content caching

See "content delivery"

content delivery

On the Internet, content delivery (sometimes called *content distribution*, *content distribution delivery*, or *content caching*) is the service of copying the pages of a Web site to geographically dispersed **servers** and, when a page is requested, dynamically identifying and serving page content from the closest server to the user, enabling faster delivery. Typically, high-traffic Web site owners and Internet service providers (**ISPs**) hire the services of the company that provides content delivery.

A common content delivery approach involves the placement of **cache** servers at major Internet access points around the world and the use of a special routing code that redirects a Web page request (technically, a Hypertext Transfer Protocol—**HTTP**—request) to the closest server. When the Web user clicks on a **URL** that is content-delivery enabled, the content delivery network re-routes that user's request away from the site's originating server to a cache server closer to the user. The cache server determines what content in the request exists in the cache, serves that content, and retrieves any non-cached content from the originating server. Any new content is also cached locally. Other than faster loading times, the process is generally transparent to the user, except that the URL served may be different than the one requested.

The three main techniques for content delivery are: HTTP redirection, Internet Protocol (IP) redirection, and domain name system (**DNS**) redirection. In general, DNS redirection is the most effective technique.

Content delivery can also be used for specific high-traffic events such as live Web broadcasts by continually dispersing content from the originating server to other servers via **satellite** links.

Content delivery is similar to but more selective and dynamic than the simple copying or **mirror site** of a Web site to one or several geographically dispersed servers.

content distribution

See “content delivery”

content management system

A content management system (CMS) is a system used to manage the content of a **Web site**. Typically, a CMS consists of two elements: the content management application (CMA) and the content delivery application (CDA). The CMA element allows the content manager or author, who may not know Hypertext Markup Language (**HTML**), to manage the creation, modification, and removal of content from a Web site without needing the expertise of a **Webmaster**. The CDA element uses and compiles that information to update the Web site. The features of a CMS system vary, but most include Web-based publishing, format management, revision control, and indexing, search, and retrieval.

The Web-based publishing feature allows individuals to use a **template** or a set of templates approved by the organization, as well as wizards and other tools to create or modify Web content. The format management feature allows documents including **legacy** electronic documents and scanned paper documents to be formatted into HTML or Portable Document Format (**PDF**) for the Web site. The revision control feature allows content to be updated to a newer version or restored to a previous version. Revision control also tracks any changes made to files by individuals. An additional feature is indexing, search, and retrieval. A CMS system indexes all data within an organization. Individuals can then search for data using keywords, which the CMS system retrieves.

A CMS system may also provide tools for one-to-one marketing. One-to-one marketing is the ability of a Web site to tailor its content and advertising to a user’s specific characteristics using information provided by the user or gathered by the site (for example, a particular user’s page sequence pattern). For example, if you visit a **search engine** and search for “**digital camera**,” the advertising banners will advertise businesses that sell digital cameras instead of businesses that sell garden products.

Two factors must be considered before an organization decides to invest in a CMS. First, an organization’s size and geographic dispersion must be considered especially if an organization is spread out over several countries. For these organizations, the transition to CMS is more difficult. Secondly, the diversity of the electronic data forms used

within an organization must be considered. If an organization uses text documents, graphics, video, audio, and diagrams to convey information, the content will be more difficult to manage.

Content Protection for Removable Media

Content Protection for Removable Media (CPRM) is a hardware-based technology designed to enforce copy protection restrictions through built-in mechanisms in **storage media** that would prevent unauthorized **file** copying.

Based on a technology called *broadcast encryption* that was developed by Amos Fiat and Moni Naor in 1993, the CPRM system would be used to incorporate digital tags into storage media, such as recordable CDs (**CD-R**, **CD-RW**) and **flash memory** cards for **MP3** players.

CPRM was developed by 4C Entity, an industry consortium originally made up of Intel, IBM, Matsushita, and Toshiba. The system has been highly controversial, because it could be used not only with removable media, but as a part of every new hard drive produced as well. Technical Committee T13 (a coalition of companies that produce both flash memory and hard drives) considered adopting CPRM as an industry standard, but has since given approval to an alternative plan in development at Phoenix Technologies that would be used for other purposes—such as security mechanisms on removable media—in addition to copy protection.

Content Scrambling System

Content Scrambling System (CSS) is a data **encryption** and **authentication** method used to protect digital versatile disk (**DVD**) movies from being illegally copied, distributed, and viewed from other devices, such as computer hard drives. CSS is one of several copy-protection methods currently used in today’s DVDs.

The CSS method was developed by members of the DVD Copy Control Association (DVDCCA). This association includes companies in the U.S. motion picture industry (members of the MPAA) and the consumer electronics industry. The Matsushita and Toshiba companies are largely credited with the first main development efforts of the CSS method for encryption and decryption of DVD movies.

In general, the CSS method encrypts (scrambles) the video files on a DVD to prevent illegal viewing or copying. In order to view any video files found on the DVD, the user must use a hardware device that is CSS-licensed to decrypt, or decode, the data in the video file. One such hardware device is a DVD-ROM (DVD-read only memory) device that can be installed with a computer or a specially designed TV in order to view DVD movies. Another possible device could be the hard disk of a personal computer.

DVD disc manufacturers or DVD-ROM manufacturers must first be licensed to use CSS before they can produce discs or DVD-ROMs that will successfully encrypt or decrypt CSS-protected video files. Once a DVD-ROM manufacturer is licensed to use CSS, the manufacturer receives one of 400 keys which are stored in a locked section on every CSS-supported disc.

The DVD-ROM then uses this key information to decode the video file on the DVD and display the related movie. The actual operation of CSS involves the use of a decryption algorithm that mixes the key information exchanged between the disc and the hardware device in order to produce a unique key that will successfully decrypt the movie or video file for viewing.

As with many encryption methods of the past, CSS came under intense scrutiny in October 1999 when it was reported that a 16-year-old Norwegian programmer cracked the CSS code and posted the decryption method (quickly coined *DeCSS*) on the Internet. This action, and the subsequent postings of *DeCSS* code elsewhere on the Internet, heralded a series of lawsuits from the DVDCCA. In response, some pro-*DeCSS* organizations also sprouted up to protest what they perceived of as a lack of rights to freely distribute the reverse-engineered, CSS code for other programming uses.

Lawsuits over the future rights to access the CSS/*deCSS* code are still being waged today. The DVDCCA maintains that CSS can be licensed for free to any manufacturer who agrees to follow the terms of its CSS license.

contiguity

Contiguity (from Latin *contiguus* and *contingere*, to have contact with) is the state of being in close proximity with or even touching another object. In data processing, a group of data fields that are contiguous (rather than dispersed among other groups or locations) consists of fields that can be processed one after the other in sequence.

control network

A control network is a **network** of **nodes** that collectively monitor, sense, and control or enable control of an environment for a particular purpose. A home appliance network is a good example of a control network. In fact, thousands of control networks already exist in everyday life in automobiles, refrigerators, traffic light controls, city lighting systems, and on factory floors. Control networks vary enormously in the number of nodes (from three to thousands) in the network and in their complexity. Unlike networks that people use to communicate with each other, control networks tend to be invisible. In the future, control networks are expected to become an important aspect of what is sometimes called *ubiquitous computing*.

Communication between nodes in a control network may be peer-to-peer or master-slave. The nodes in some control networks contain three processors in one: two dedicated to

moving data within the network and one for the specialized program associated with that node. This modularity makes it cheaper and faster to build new processors for control networks. Increasingly, control networks are being made from off-the-shelf hardware and software components.

One future role for control networks will be as the controllers of microelectromechanical systems (**MEMS**), sometimes referred to as *smart matter*. Because it greatly expands the number of items in the world that can be uniquely addressed in a network, **IPv6**, a new version of the Internet Protocol (**IP**), is expected to make remote access and control of all kinds of devices possible, including every networked appliance at your office or at home. Sun Microsystem's **Jini**, will make it easy to plug new devices into a control network and have their characteristics immediately recognized by the system.

conventional memory

DOS memory, sometimes referred to as conventional memory, refers to the **memory**-addressing scheme used in the original IBM and compatible PCs. These came with only one **operating system**, **Disk Operating System**, and this operating system had to be designed to work with the PC's **microprocessor**, the Intel 8088. Because of 8088 engineering limitations, storage or memory addresses were limited to a maximum of one **megabyte**. (Later, of course, PC's came with 2, 4, 8, and today's common 16 and 32 megabytes of RAM.) At the time, however, one megabyte was considered a rather large amount of memory to be able to access.

A certain amount of the random access memory was reserved as a place to load in the **basic input/output system** or initializing program, another space was reserved for **buffer** areas for display data, and another space for **interrupt** data, and so forth. The remaining 640 **kilobytes** of memory could be used by the DOS operating system (which was relatively small) and **application** programs.

The reason that all of this is not academic is that, as new microprocessors and operating systems have been developed, many older programs written with the original memory addressing limitations need to continue running in the newer systems. This means that the newer systems have had to accommodate the older programs so that they can run in the original limited 640 kilobyte contiguous address range. A program that is run with this constraint is described as running in **protected mode**. (Programs running without this constraint are described as running in **protected mode**.)

With the successors to the 8088, the 80286 and 80386 microprocessors, available memory increased considerably, with up to 15 megabytes possible in a 286 and up to almost 4 **gigabyte** of RAM possible in a 386. This extra memory above the original one megabyte that DOS was designed to address is called *extended memory*. Being able to address extended memory means running in protected mode.

In general, DOS applications can only run in real mode since DOS itself requires the memory constraint. However, some programs have been developed called *DOS extenders* that can be compiled with the application and provide a built-in memory management capability. In order for multiple DOS programs with memory extenders to run concurrently, some common approach was required so that programs could share the extended memory effectively. Several standards developed to manage this sharing: XMS (Extended Memory Specification), VCPI (Virtual Control Program Interface), and **DOS Protected Mode Interface** (DOS protected mode interface).

convergence

In information technology, convergence is a term for the combining of personal computers, telecommunication, and television into a user experience that is accessible to everyone. In the U.S., an estimated 30% of homes have computers with modems. Virtually, 100% of homes have a TV set. Studies show a large populace of TV users who would embrace the Internet, video-on-demand, and greater interaction with content, but who are diffident about buying and using a personal computer. For these reasons, both the computer and the television industries are embarked on bringing digital TV and the Internet to a larger market.

Convergence is not simply an issue of technology, but also of culture and life style. In general, TV is visual, not very interactive (except for changing channels), oriented primarily toward entertainment and news. Displays are large and TVs are easy to operate, requiring almost no education to use. Personal computers, in spite of their graphical user interfaces (**GUI**) tend to be more text-oriented, highly interactive, oriented in terms of purpose and content toward business and education uses. Displays are smaller. Computers can be very challenging to use and usually require formal education or a certain personal learning curve.

Convergence is already underway with **WebTV**, which pipes the World Wide Web to a slightly-modified TV set with a set-top box from an ordinary phone line and provides a degree of interactivity. A number of interactive games designed for the TV environment can also be played over the Internet. Broadcasting companies such as NBC have partnered with computer companies such as Microsoft for TV program content.

A major barrier to more rapid convergence is the large investment required to bring **cable TV** to households, both by cable access providers and individual households. **Satellite wireless** service is another approach that is only beginning to bring its subscribers access to the Internet. Digital Subscriber Line (**DSL**) technologies offer the possibility of sufficient **bandwidth** connections over ordinary phone wires for streaming video to TV sets.

A consortium of leading computer and telecommunication companies including Compaq, IBM, and Microsoft are working toward common standards that will help speed up convergence and hope to sponsor a standard for a relatively low-cost **digital TV**. They have endorsed a subset of the recommendations of the Advanced Television System Committee (ATSC) that would speed up a transition to digital TV and so that personal computers could have the ability to receive digital video and data.

Conversational Monitor System

CMS (Conversational Monitor System) is a product that comes with IBM's **VM/ESA operating system** and allows each of many simultaneous interactive users to appear to have an entire mainframe computer at their personal disposal. Almost as old as IBM's **MVS** operating system, VM/ESA (generally known as "VM") and CMS originated at IBM's Cambridge Scientific Center in 1964. VM provides an extra layer of programming below an operating system, called the *control program* that handles the actual machine operation of the computer. The control program lets each operating system, such as MVS and CMS, appear to be in sole charge of the computer—effectively, creating a *virtual machine*. CMS goes a step further and lets each CMS user appear to have their own personal operating system.

Users of a VM system typically log on to VM first and then (virtually) start their own personal CMS (by entering the command: `i cms`). Thereafter, the user can communicate with other active users, send mail, develop and run applications, and use many standard applications and tools that have been developed over VM and CMS's evolution.

COO

See "Cell of Origin"

cookie

A cookie is information that a **Web site** puts on your **hard disk** so that it can remember something about you at a later time. (More technically, it is information for future use that is stored by the **server** on the **client** side of a **client/server** communication.) Typically, a cookie records your preferences when using a particular site. Using the Web's Hypertext Transfer Protocol (**HTTP**), each request for a Web page is independent of all other requests. For this reason, the Web page server has no memory of what pages it has sent to a user previously or anything about your previous visits. A cookie is a mechanism that allows the **server** to store its own information about a user on the user's own computer. You can view the cookies that have been stored on your hard disk (although the content stored in each cookie may not make much sense to you). The location of the cookies depends on the browser. Internet Explorer stores each cookie as a

separate file under a Windows subdirectory. Netscape stores all cookies in a single cookies.txt file. **Opera** stores them in a single cookies.dat file.

Cookies are commonly used to rotate the banner ads that a site sends so that it doesn't keep sending the same ad as it sends you a succession of requested pages. They can also be used to customize pages for you based on your browser type or other information you may have provided the Web site. Web users must agree to let cookies be saved for them, but, in general, it helps Web sites to serve users better.

cool

On the World Wide Web, cool has a number of meanings, including:

- Engaging
- Laid-back, understated
- In tune with the latest thinking, even a little ahead of it
- Technically or graphically impressive

The term "cool" seems to have originated among jazz musicians in the 1940s. In *Understanding Media*, Marshall McLuhan described television as a "cool" medium (unlike the "hot" media of radio and print) because it is sensorily more complex and involving. "A cool medium," said Professor McLuhan, "whether the spoken word or the manuscript or TV, leaves much more for the listener or user to do than a hot medium." A composite of several media (photographs, print, animated images, movies, sound, telephone conversations, posted notes...) and also in itself a new medium of over 100 million potential "publishers" and interactors, the Web itself seems much closer to McLuhan's "cool."

co-opetition

Co-opetition is a business strategy based on a combination of cooperation and competition, derived from an understanding that business competitors can benefit when they work together. The co-opetition business model is based on *games theory*, a scientific approach (developed during World War II) to understanding various strategies and outcomes through specifically designed games. Traditional business philosophy translates to games theory's *zero-sum game* in which the winner takes all, and the loser is left empty-handed; proponents of co-opetition claim that it can lead to a *plus-sum game*, in which the sum of what is gained by all players is greater than the combined sum of what the players entered the game with.

The co-opetition model starts out with a diagramming process called the *value net*, which is represented as a diamond shape, with four defined player designations at the corners: customers, suppliers, competitors and *complementors*. Complementors are defined as players whose product adds value to yours, the way, for example, that software products gain value because hardware products coexist with

them, and vice-versa. In comparison, a competitor is defined as someone whose product makes your product less valued, the way, for example, a second brand of toothpaste would make one that had previously been the only one less valued.

The game of business is then broken down into its PARTS (players, added values, rules, tactics, and scope) as a means of viewing practices and strategies. *Added value* focuses on ways to improve products and services to find ways of making more money from an existing customer base. *Rules* specify ways of attracting customers with strategies such as price-matching. *Tactics* are the practices sometimes used to take away a competitor's likely market share, for example, announcing an upcoming (and possibly non-existent) new and improved product when a competitor's product is released. *Scope* is the final part, used to take a broader prospective and create links between competitor's games and interests and see how co-opetition can benefit the players.

Although several people have been credited with inventing the term *co-opetition*, including Sam Albert, Microsoft's John Lauer, and Ray Noorda, Novell's founder, its principles and practices were fully articulated originally in the 1996 book, *Co-opetition*, by Harvard and Yale business professors, Adam M. Brandenburger and Barry J. Nalebuff.

Coordinated Universal Time

Coordinated Universal Time (abbreviated as UTC, and therefore often spelled out as Universal Time Coordinated and sometimes as Universal Coordinated Time) is the standard time common to every place in the world. Formerly and still widely called Greenwich Mean Time (GMT) and also World Time, UTC nominally reflects the mean solar time along the Earth's prime meridian. (The prime meridian is 0 longitude in the 360 lines of longitude on Earth. There are 179 meridians toward the East and 179 toward the West. The 180th meridian is also called the International Date Line.) The prime meridian is arbitrarily based on the meridian that runs through the Greenwich Observatory outside of London, where the present system originated. The UTC is based on an atomic clock to which adjustments of a second (called a *leap second*) are sometimes made to allow for variations in the solar cycle.

Coordinated Universal Time is expressed using a 24-hour clock but can be converted into a 12-hour clock (AM and PM). UTC is used in plane and ship navigation, where it also sometimes known as **Zulu**. UTC uses the **Gregorian calendar**.

UTC was defined by the International Radio Consultative Committee (CCIR), a predecessor organization of the **ITU-TS**, and is maintained by the Bureau International des Poids et Mesures (BIPM).

COPS

COPS (Common Open Policy Service Protocol) is a proposed standard **protocol** for exchanging network **policy** information between a policy decision point (PDP) in a network and policy enforcement points (PEPs) as part of overall Quality of Service (**QoS**)—the allocation of network traffic resources according to desired priorities of service. The policy decision point might be a network server controlled directly by the network administrator who enters policy statements about which kinds of traffic (voice, bulk data, video, teleconferencing, and so forth) should get the highest priority. The policy enforcement points might be **routers** or layer 3 switches that implement the policy choices as traffic moves through the network. Currently, COPS is designed for use with the Resource Reservation Protocol (**RSVP**), which lets you allocate traffic priorities in advance for temporary high-bandwidth requirements (for example, video broadcasts or multicasts). It is possible that COPS will be extended to be a general policy communications protocol.

In operation, RSVP makes two determinations when an RSVP request arrives at a router or **layer 3** switch. First, it determines whether there are enough resources to satisfy the **bandwidth** reservation request. If there are, RSVP determines whether the user is authorized to make the reservation. The first determination is known as the *admission control* decision; the second is known as the *policy control* decision. COPS allows the router or layer 3 switch to communicate with the policy decision point about whether the request for the bandwidth reservation should be permitted. Without COPS, all resources would be reserved on a first come-first served basis only, and one or more requesters could easily take all the bandwidth.

The current COPS protocol is specified in an Internet-Draft working document of the Internet Engineering Task Force (**IETF**).

copyleft

Copyleft is the idea and the specific stipulation when distributing software that the user will be able to copy it freely, examine and modify the source code, and redistribute the software to others (free or priced) as long as the redistributed software is also passed along with the copyleft stipulation. The term was originated by Richard Stallman and the **Free Software Foundation**. Copyleft favors the software user's rights and convenience over the commercial interests of the software makers. It also reflects the belief that freer redistribution and modification of software would encourage users to make improvements to it. ("Free software" is not the same as **freeware**, which is usually distributed with copyright restrictions.)

Stallman and his adherents do not object to the price or profit aspects of creation and redistribution of software—only to the current restrictions placed on who can use how many copies of the software and how and whether the software can be modified and redistributed.

The de facto collaboration that developed and refined **UNIX** and other collegially-developed programs led the FSF to the idea of "free" software and copyleft. In 1983, the FSF began developing a "free software" project that would both demonstrate the concept while providing value to users. The project was called **GNU**, an operating system similar to a UNIX system. GNU and its various components are currently available and are distributed with copyleft stipulations. New software is being developed.

CORBA

Common Object Request Broker Architecture (CORBA) is an architecture and specification for creating, distributing, and managing **distributed** program **objects** in a network. It allows programs at different locations and developed by different vendors to communicate in a network through an "interface broker." CORBA was developed by a consortium of vendors through the Object Management Group (**OMG**), which currently includes over 500 member companies. Both International Organization for Standardization (**ISO**) and X/Open have sanctioned CORBA as the standard architecture for distributed objects (which are also known as **components**). CORBA 3 is the latest level.

The essential concept in CORBA is the Object Request Broker (**ORB**). ORB support in a network of clients and servers on different computers means that a client program (which may itself be an **object**) can request services from a server program or object without having to understand where the server is in a distributed network or what the interface to the server program looks like. To make requests or return replies between the ORBs, programs use the General Inter-ORB Protocol (GIOP) and, for the Internet, its Internet Inter-ORB Protocol (**IIOP**). IIOP maps GIOP requests and replies to the Internet's Transmission Control Protocol (**TCP**) layer in each computer.

A notable hold-out from CORBA is Microsoft, which has its own distributed object architecture, the Distributed Component Object Model (**DCOM**). However, CORBA and Microsoft have agreed on a gateway approach so that a client object developed with the Component Object Model will be able to communicate with a CORBA server (and vice versa).

Distributed Computing Environment (**DCE**), a distributed programming architecture that preceded the trend toward object-oriented programming and CORBA, is currently used by a number of large companies. DCE will perhaps continue to exist along with CORBA and there will be "bridges" between the two.

More information is available in our definitions of **Internet Inter-ORB Protocol** and **Object Request Broker**.

cordless mouse

A cordless **mouse** frees you from cord problems. It connects to your computer with a radio (rather than an infrared) signal, powered by two AAA batteries. One manufacturer, Logitech, offers two versions of a three-button mouse; one includes a button positioned for the thumb (for right-handed users). The buttons can be assigned different uses during system setup.

core competency

A core competency is fundamental knowledge, ability, or expertise in a specific subject area or skill set. For example, an individual who becomes certified as a Microsoft Certified Software Engineer (**MCSE**) is said to have a core competency in certain Microsoft systems and networks. Companies with specific strengths in the marketplace, such as data storage or the development of accounting applications, can be said to have a core competency in that area. The *core* part of the term indicates that the individual has a strong basis from which to gain the additional competence to do a specific job or that a company has a strong basis from which to develop additional products.

core dump

A core dump is the printing or the copying to a more permanent medium (such as a **hard disk**) the contents of random access memory (**RAM**) at one moment in time. One can think of it as a full-length "snapshot" of RAM. A core dump is taken mainly for the purpose of debugging a program. With the arrival of higher-level languages and interactive debugging, few problems require a core dump these days. It's more likely to be used by specialized programmers who maintain and occasionally have to debug problems in **operating system**.

The "core" refers to the ferrite cores of earlier memory technology. In some earlier operating systems, certain system errors would automatically result in the performing of a core dump. Typically, a core dump or actually the report that results from the core dump presents the RAM contents as a formatted series of lines that indicate memory locations and the **hexadecimal** values recorded at each location. Additional information tells exactly which instruction was executing at the time the core dump was initiated.

IBM's dictionary does not include the term and Microsoft mentions it as an antiquated term. *The New Hacker's Dictionary* says the term is from the "Iron Age."

A *dump* is a more general term that includes the copying of a large portion of one storage medium to another storage medium or to a printer, display, or other output device. A dump report is formatted for readability.

The term is sometimes applied to human beings as a variation of *brain dump*.

corporate portal

See "corportal"

corportal

Corportal is short for "corporate portal." Many corporations are building and, in some cases, rebuilding their **Web sites** along the model of the **enterprise information portal**, a model that emphasizes the exploitation of a company's information resources. A corportal can be internal (an intranet), a public site, or, with appropriate safeguards, both combined.

CoS

See "Class of Service"

COTS

See "commercial off-the-shelf"

coulomb

The coulomb (symbolized C) is the standard unit of electric charge in the International System of Units (**SI**). It is a dimensionless quantity, sharing this aspect with the **mole**. A quantity of 1 C is equal to approximately 6.24×10^{18} , or 6.24 quintillion.

In terms of SI base units, the coulomb is the equivalent of one **ampere-second**. Conversely, an electric **current** of A represents 1 C of unit electric charge carriers flowing past a specific point in 1 s. The unit electric charge is the amount of charge contained in a single **electron**. Thus, 6.24×10^{18} electrons have 1 C of charge. This is also true of 6.24×10^{18} positrons or 6.24×10^{18} protons, although these two types of particle carry charge of opposite **polarity** to that of the electron.

The force with which two electrically charged bodies attract or repel one another depends on the product of the charges (in coulombs) in both objects, and also on the distance between the objects. If the polarities are the same (negative/negative or positive/positive), the so-called coulomb force is repulsive; if the polarities are opposite (negative/positive or positive/negative), the force is attractive. For any two charged bodies, the coulomb force decreases in proportion to the square of the distance between their charge centers.

coulomb per meter cubed

The coulomb per meter cubed (symbolized $C \cdot m^{-3}$) is the unit of electric charge density. Reduced to base units in the International System of Units (**SI**), $1 C \cdot m^{-3}$ is equivalent to one **ampere second per meter cubed** ($1 A \cdot s \cdot m^{-3}$).

Suppose there is a globe having volume of one **meter** cubed, and it is supplied with one **coulomb** of charge with respect to electrical ground. Then the average charge density in the globe is $1 \text{ C} \cdot \text{m}^{-3}$. The local charge density might not be uniform throughout the globe, but might instead be concentrated near the surface, especially if the charge is comprised of an excess of **electrons** (that is, a negative charge). This is because particles of like charge tend to repel each other. In that case, the local charge density near the center of the globe will be less than $1 \text{ C} \cdot \text{m}^{-3}$, and the local charge density near the surface will be greater than $1 \text{ C} \cdot \text{m}^{-3}$.

If the charge on the globe is doubled, then the average charge density will become $2 \text{ C} \cdot \text{m}^{-3}$. If the diameter of the globe is cut in half while the charge remains the same, then the average charge density will increase by a factor of 8, because the volume will become $1/8$ ($1/2^3$) as great as before.

Also see **electric field**, **coulomb**, **meter cubed**, **coulomb per meter squared**, and International System of Units (SI).

counter

On the Web, a counter is a program that counts and typically displays how many people have visited an **HTML** page (usually the **home page**). Many sites include a counter, either as a matter of interest or to show that the site is popular. The counter can be part of the **common gateway interface** application that logs and analyzes requests.

At least one company provides the service of monitoring sites that request it, counting home page requests, and updating the number of visitors each time the home page is sent. A third-party who monitors the counting of site visitors is called an **auditor**.

counting board

Historically, a counting board was a portable flat surface, usually of wood or stone, on which a user placed objects such as pebbles or beads for the purpose of maintaining a count of something. The counting board is thought to have originated so that you didn't have to draw lines on the ground or in sand as points of reference for counters every time you needed to add figures up. The oldest surviving counting board was discovered on the island of Salamis in 1899 and was used in Babylonia, circa 300 B.C.

The counting board led to the **abacus**.

courseware

Courseware, a term that combines the words *course* with *software*, is educational material intended as kits for teachers or trainers or as tutorials for students, usually packaged for use with a computer. Courseware can encompass any knowledge area, but information technology subjects are most common. Courseware is frequently used for delivering education about the personal computer and its most popular business applications, such as word processing and

spreadsheet programs. Courseware is also widely used in information technology industry certification programs, such as the Microsoft Certified Systems Engineer (**MCSE**) and the Computing Technology Industry Association's **A+** examination.

Courseware can include:

- Material for instructor-led classes
- Material for self-directed computer-based training (CBT)
- Web sites that offer interactive tutorials
- Material that is coordinated with distance learning, such as live classes conducted over the Internet
- Videos for use individually or as part of classes

The **CD-ROM** is the most common means of delivering courseware that is not offered online. For teachers and trainers, courseware content may include set-up information, a course plan, teaching notes, and exercises.

CPI

1) For a given **font**, **cpi** (characters per inch) is the number of typographic **character** that will fit on each inch of a printed line. The measurement applies mainly to *monospace* (*fixed-width*) fonts. Fonts with characters of proportional (varying) widths have an average cpi.

2) **cpi** (cycles per instruction, or clocks per instruction) is the number of computer **clock speed** cycles (alternating current pulses) that occur while a computer **instruction** is being executed (performed by the computer processor). The number of cycles per instruction can be reduced by using **pipelining**. In some *superscalar* processors, more than one instruction can be performed during a single clock cycle.

3) **CPI** (Common Programming Interface) is the application program interface (**API**) specified as part of IBM's proprietary software architecture, the Systems Application Architecture (**SNA**).

CPNI

In the U.S., **CPNI** (Customer Proprietary Network Information) is information that telecommunications services such as local, long distance, and **wireless** telephone companies acquire about their subscribers. It includes not only what services they use but their amount and type of usage. The **Telecommunications Act of 1996** together with clarifications from the Federal Communications Commission (FCC) generally prohibits the use of that information without customer permission, even for the purpose of marketing the customers other services. In the case of customers who switch to other service providers, the original service provider is prohibited from using the information to try to get the customer back. CPNI includes such information as optional services subscribed to, current charges, directory assistance charges, usage data, and calling patterns.

CRA

See "customer relationship analysis"

cracker

A cracker is someone who breaks into someone else's computer system, often on a network; bypasses passwords or licenses in computer programs; or in other ways intentionally breaches computer security. A cracker can be doing this for profit, maliciously, for some altruistic purpose or cause, or because the challenge is there. Some breaking-and-entering has been done ostensibly to point out weaknesses in a site's security system.

The term "cracker" is not to be confused with "**hacker**." Hackers generally deplore cracking. However, as Eric Raymond, compiler of *The New Hacker's Dictionary* notes, some journalists ascribe break-ins to "hackers."

A classic story of the tracking down of a cracker on the Internet who was breaking into U.S. military and other computers is told in Clifford Stoll's *The Cuckoo's Egg*.

cracking

See "brute force cracking"

crash

A crash is the sudden failure of a software application or **operating system** or of a hardware device such as a **hard disk**.

crawler

A crawler is a program that visits Web sites and reads their pages and other information in order to create entries for a **search engine** index. The major search engines on the Web all have such a program, which is also known as a "spider" or a "bot." Crawlers are typically programmed to visit sites that have been submitted by their owners as new or updated. Entire sites or specific pages can be selectively visited and indexed. Crawlers apparently gained the name because they crawl through a site a page at a time, following the links to other pages on the site until all pages have been read.

The crawler for the **AltaVista** search engine and its Web site is called **Scooter**. Scooter adheres to the rules of politeness for Web crawlers that are specified in the Standard for Robot Exclusion (SRE). It asks each server which files should be excluded from being indexed. It does not (or can not) go

through **firewalls**. And it uses a special **algorithm** for waiting between successive server requests so that it doesn't affect response time for other users.

CRC

See "cyclic redundancy checking"

critical section routine

In computers, a critical section routine is an approach to the problem of two or more programs competing for the same resource at the same time. Imagine that two programs want to increment a counter. If both do it at the same time: fetch the **operand**, increment it, and store back the incremented value, then one of the increments will be lost. On today's processors, the programs can use an **atomic** read-modify-write instruction, such as fetch-and-op, compare-and-swap, or exchange. On early processors, these instructions did not exist; the problem was to accomplish the incrementing atomically, using only ordinary **assembler** instructions. The problem was defined and first solved by Edsger Dijkstra. "Critical section routine" was his name for the code that solved the problem.

CRM

See "customer relationship management"

CRM analytics

CRM (**customer relationship management**) analytics comprises all programming that analyzes data about an enterprise's customers and presents it so that better and quicker business decisions can be made. CRM analytics can be considered a form of online analytical processing (**OLAP**) and may employ **data mining**. As Web sites have added a new and often faster way to interact with customers, the opportunity and the need to turn data collected about customers into useful information has become generally apparent. As a result, a number of software companies have developed products that do customer data analysis.

According to an article in *InfoWorld*, CRM analytics can provide customer segmentation groupings (for example, at its simplest, dividing customers into those most and least likely to repurchase a product); profitability analysis (which customers lead to the most profit over time); personalization (the ability to market to individual customers based on the data collected about them); event monitoring (for example, when a customer reaches a certain dollar volume of purchases); what-if scenarios (how likely is a customer or customer category that bought one product to buy a similar one); and predictive modeling (for example, comparing various product development plans in terms of likely future success given the customer knowledge base). Data collection and analysis are viewed as a continuing and iterative

process and ideally over time business decisions are refined based on feedback from earlier analysis and consequent decisions.

Benefits of CRM analytics are said to lead not only to better and more productive customer relations in terms of sales and service but also to improvement in **supply chain management** (lower inventory and speedier delivery) and thus lower costs and more competitive pricing.

One of the major challenges implicit in CRM analytics is how to integrate the analytical software with existing **legacy** systems as well as with other new systems.

A new area of application and data collection has to do with Web site customer usage.

CRON script

A **CRON script** is a list of one or more **commands** to a computer **operating system** or application server that are to be executed at a specified time. Each command is executed when its triggering time arrives. In **UNIX-based operating systems**, the **crontab** command is a user interface command that creates or changes a file (called a *crontab file*). This file contains a list of UNIX shell commands, each with a specified time of execution. A CRON script is similar.

crontab

crontab is a **UNIX command** that creates a table or list of commands, each of which is to be executed by the operating system at a specified time. *crontab* is used to create the *crontab file* (the list) and later used to change the previously created crontab file.

Also see **CRON script**.

cross section

1) A cross section is a cut through something (such as a **coaxial cable**) at an angle perpendicular to its axis in order to view its interior structure. A well-known example is a cross section of a tree that shows its growth rings and tells its age.

2) Somewhat less precisely, a cross section can be any view of something that shows a representative portion of each of its parts. For example, a cross section of a **Web site** might show a representative **page** of content at each of its hierarchical levels. A cross section of a Web site audience would indicate its demographics (types of people who used the site in terms of gender, age, occupation, and so forth).

cross-bar switch

In a network, a cross-bar switch is a device that is capable of channeling data between any two devices that are attached to it up to its maximum number of **ports**. The paths set up

between devices can be fixed for some duration or changed when desired and each device-to-device path (going through the **switch**) is usually fixed for some period.

Cross-bar **topology** can be contrasted with **bus** topology, an arrangement in which there is only one path that all devices share. Traditionally, computers have been connected to storage devices with a large bus. A major advantage of cross-bar switching is that, as the traffic between any two devices increases, it does not affect traffic between other devices. In addition to offering more flexibility, a cross-bar switch environment offers greater **scalability** than a bus environment.

In an IBM **mainframe** environment, the **ESCON** director is an example of a cross-bar switch.

crossfade

In digital audio production, a crossfade is editing that makes a smooth transition between two audio files. In **analog** days, crossfades required dubbing the inputs of two source tapes onto a new tape while manually turning down the volume of one source tape while turning up the other, a relatively cumbersome procedure. Crossfading became easier to achieve with the invention of the computer-based digital audio editor. A digital editor allows two or more files to be crossfaded with the fade length limited only by the amount of audio contained in the source files. The edit consists of fading out one source file while fading in the other. This method creates a smooth transition because for a short period of time the listener hears both files playing simultaneously.

A crossfade is the opposite of a butt splice. In a butt splice, the end of the first file is joined to the beginning of the second file.

crossover cable

A crossover cable is a cable that is used to interconnect two computers by "crossing over" (reversing) their respective **pin** contacts. Either an **RS-232C** or an **registered jack** connection is possible. A crossover cable is sometimes known as a **null modem**. Possible reasons to connect two computers directly to each other include:

- Playing a game competitively (one person at each computer) with fast response time
- Testing one computer by examining its behavior at the other computer
- Saving the cost of a **hub** when you want to interconnect two devices in the same home or office

cross-post

On a Web or bulletin board discussion list or a **Usenet newsgroup**, a cross-post is the posting (submission) of an article to more than one discussion list or newsgroup at a time. On Usenet, the cross-post can be done in such a way

that all newsgroup users can link to, read, and, if desired, respond to one copy of the posting on one of the newsgroups. Each of the other posted newsgroups contains a reference to it.

Cross-post is also used to mean simply copying the posting to each of a number of discussion groups. Most discussion groups and newsgroups provide rules about how and whether to submit articles as cross-posts.

crosstalk

Crosstalk is a disturbance caused by the electric or magnetic fields of one telecommunication **signal** affecting a signal in an adjacent **circuit**. In a telephone circuit, crosstalk can result in your hearing part of a voice conversation from another circuit. The phenomenon that causes crosstalk is called electromagnetic interference (EMI). It can occur in microcircuits within computers and audio equipment as well as within network circuits. The term is also applied to optical signals that interfere with each other.

CRT

See "cathode ray tube"

crumb

In computers, crumb is jargon for two **bits** (that is, two **binary digits**).

According to the *Jargon File*, synonyms are: quad, taste, and tasty. The term is rarely used.

Crusoe

Crusoe is a family of "smart" microprocessors from **Transmeta** that combines a relatively simple, low-powered hardware **processor** with software that makes the hardware processor look like an **x86** Intel processor (such as a **Pentium III**). Because Crusoe requires only one-fourth of the usual number of **transistors**, the processor has a small power requirement. As a result, Crusoe is expected to introduce a new era of mobile devices that can run all day without requiring a **battery** recharge.

The hardware processor operates with very long instruction word (**VLIW**) **instructions**. The VLIW instructions are developed by the software, which is on **flash memory** and which Transmeta calls its Code Morphing Software. The software takes the **x86** instructions from the **operating system** or applications and develops them into optimized VLIW instructions for the hardware processor.

Initially, the Crusoe family consists of two processors:

- **The TM3120—for mobile devices weighing two pounds or less.** The speed is 333-400 **MHz** and the power requirement is low enough to allow a full day of Web browsing without a battery recharge.

- **The TM5400—for mobile PCs weighing four pounds or less.** Performance is up to 700 **MHz**, providing up to eight hours of "everyday office use" and up to four hours of playing DVD movies without needing a recharge.

Crusoe processors are expected to appear in mobile devices, including the *Web pad*, the notebook computer, and the **wearable computer**.

cryptanalysis

Cryptanalysis refers to the study of ciphers, **ciphertext**, or cryptosystems (that is, to secret code systems) with a view to finding weaknesses in them that will permit retrieval of the **plaintext** from the ciphertext, without necessarily knowing the **key** or the **algorithm**. This is known as *breaking* the cipher, ciphertext, or cryptosystem.

Breaking is sometimes used interchangeably with *weakening*. This refers to finding a property (fault) in the design or implementation of the **cipher** that reduces the number of keys required in a brute force attack (that is, simply trying every possible key until the correct one is found). For example, assume that a symmetric cipher implementation uses a key length of 2^{128} bits (2 to the power of 128): this means that a brute force attack would need to try up to all 2^{128} possible combinations (rounds) to be certain of finding the correct key (or, on average, 2^{127} possible combinations) to convert the ciphertext into plaintext, which is not possible given present and near future computing abilities. However, a cryptanalysis of the cipher reveals a technique that would allow the plaintext to be found in 2^{40} rounds. While not completely broken, the cipher is now much weaker and the plaintext can be found with moderate computing resources.

There are numerous techniques for performing cryptanalysis, depending on what access the cryptanalyst has to the plaintext, ciphertext, or other aspects of the cryptosystem. Below are some of the most common types of attacks:

- 1) **Known-plaintext analysis:** With this procedure, the cryptanalyst has knowledge of a portion of the plaintext from the ciphertext. Using this information, the cryptanalyst attempts to deduce the key used to produce the ciphertext.
- 2) **Chosen-plaintext analysis (also known as differential cryptanalysis):** The cryptanalyst is able to have any plaintext encrypted with a key and obtain the resulting ciphertext, but the key itself cannot be analyzed. The cryptanalyst attempts to deduce the key by comparing the entire ciphertext with the original plaintext. The **Rivest-Shamir-Adleman** encryption technique has been shown to be somewhat vulnerable to this type of analysis.
- 3) **Ciphertext-only analysis:** The cryptanalyst has no knowledge of the plaintext and must work only from the ciphertext. This requires accurate guesswork as to how a

message could be worded. It helps to have some knowledge of the literary style of the ciphertext writer and/or the general subject matter.

4) **Man-in-the-middle attack:** This differs from the above in that it involves tricking individuals into surrendering their keys. The cryptanalyst/attacker places him or herself in the communication channel between two parties who wish to exchange their keys for secure communication (via asymmetric or **public key infrastructure** cryptography). The cryptanalyst/attacker then performs a key exchange with each party, with the original parties believing they are exchanging keys with each other. The two parties then end up using keys that are known to the cryptanalyst/attacker. This type of attack can be defeated by the use of a **hash function**.

5) **Timing/differential power analysis:** This is a new technique made public in June 1998, particularly useful against the **smart card**, that measures differences in electrical consumption over a period of time when a microchip performs a function to secure information. This technique can be used to gain information about key computations used in the encryption algorithm and other functions pertaining to security. The technique can be rendered less effective by introducing random noise into the computations, or altering the sequence of the executables to make it harder to monitor the power fluctuations. This type of analysis was first developed by Paul Kocher of Cryptography Research, though Bull Systems claims it knew about this type of attack over four years before.

In addition to the above, other techniques are available, such as convincing individuals to reveal passwords/keys, developing **Trojan horse** programs that steal a victim's secret key from their computer and send it back to the cryptanalyst, or tricking a victim into using a weakened cryptosystem. All of these are valid techniques in cryptanalysis, even though they may be considered unorthodox.

Successful cryptanalysis is a combination of mathematics, inquisitiveness, intuition, persistence, powerful computing resources—and more often than many would like to admit—luck. However, successful cryptanalysis has made the enormous resources often devoted to it more than worthwhile: the breaking of the German Enigma code during WWII, for example, was one of the key factors in an early Allied victory.

Today, cryptanalysis is practiced by a broad range of organizations: governments try to break other governments' diplomatic and military transmissions; companies developing security products send them to cryptanalysts to test their security features and to a **hacker** or **cracker** to try to break the security of Web sites by finding weaknesses in the securing protocols. It is this constant battle between cryptographers trying to secure information and cryptanalysts trying to break cryptosystems that moves the entire body of cryptology knowledge forward.

crypto

Depending on its usage, **crypto** can be a short form for **cryptography** or for **encryption**. The term is sometimes used to broadly encompass the major aspects and issues of developing and using cryptography technologies.

cryptography

Cryptography is the science of information security. The word is derived from the Greek *kryptos*, meaning hidden. Cryptography is closely related to the disciplines of **cryptology** and **cryptanalysis**. Cryptography includes techniques such as microdots, merging words with images, and other ways to hide information in storage or transit. However, in today's computer-centric world, cryptography is most often associated with scrambling **plaintext** (ordinary text, sometimes referred to as cleartext) into **ciphertext** (a process called **encryption**), then back again (known as **decryption**). Individuals who practice this field are known as cryptographers.

Modern cryptography concerns itself with the following four objectives:

- 1) **Confidentiality** (the information cannot be understood by anyone for whom it was unintended)
- 2) **Integrity** (the information cannot be altered in storage or transit between sender and intended receiver without the alteration being detected)
- 3) **Non-repudiation** (the creator/sender of the information cannot deny at a later stage his or her intentions in the creation or transmission of the information)
- 4) **Authentication** (the sender and receiver can confirm each other's identity and the origin/destination of the information)

Procedures and **protocols** that meet some or all of the above criteria are known as cryptosystems. Cryptosystems are often thought to refer only to mathematical procedures and computer programs; however, they also include the regulation of human behavior, such as choosing hard-to-guess passwords, logging off unused systems, and not discussing sensitive procedures with outsiders.

The origin of cryptography is usually dated from about 2000 BC, with the Egyptian practice of hieroglyphics. These consisted of complex pictograms, the full meaning of which was only known to an elite few. The first known use of a modern **cipher** was by Julius Caesar (100 BC to 44 BC), who did not trust his messengers when communicating with his governors and officers. For this reason, he created a system in which each character in his messages was replaced by a character three positions ahead of it in the Roman alphabet.

In recent times, cryptography has turned into a battleground of some of the world's best mathematicians and computer scientists. The ability to securely store and transfer sensitive information has proved a critical factor in success in war and business.

Because governments do not wish certain entities in and out of their countries to have access to ways to receive and send hidden information that may be a threat to national interests, cryptography has been subject to various restrictions in many countries, ranging from limitations of the usage and export of software to the public dissemination of mathematical concepts that could be used to develop cryptosystems. However, the Internet has allowed the spread of powerful programs and, more importantly, the underlying techniques of cryptography, so that today many of the most advanced cryptosystems and ideas are now in the public domain.

cryptology

Cryptology is the mathematics, such as number theory, and the application of formulas and **algorithms**, that underpin **cryptography** and **cryptanalysis**. Since the cryptanalysis concepts are highly specialized and complex, we concentrate here only on some of the key mathematical concepts behind cryptography.

In order for data to be secured for storage or transmission, it must be transformed in such a manner that it would be difficult for an unauthorized individual to be able to discover its true meaning. To do this, certain mathematical equations are used, which are very difficult to solve unless certain strict criteria are met. The level of difficulty of solving a given equation is known as its *intractability*. These types of equations form the basis of cryptography.

Some of the most important are:

The Discrete Logarithm Problem: The best way to describe this problem is first to show how its inverse concept works. The following applies to Galois fields (groups). Assume we have a **prime number** P (a number that is not divisible except by 1 and itself, P). This P is a large prime number of over 300 digits. Let us now assume we have two other **integers**, a and b. Now say we want to find the value of N, so that value is found by the following formula:

$$N = a^b \text{ mod } P, \text{ where } 0 \leq N <= (P \cdot 1)$$

This is known as *discrete exponentiation* and is quite simple to compute. However, the opposite is true when we invert it. If we are given P, a, and N and are required to find b so that the equation is valid, then we face a tremendous level of difficulty.

This problem forms the basis for a number of **public key infrastructure** algorithms, such as **Diffie-Hellman** and ElGamal. This problem has been studied for many years and cryptography based on it has withstood many forms of attacks.

The Integer Factorization Problem: This is simple in concept. Say that one takes two prime numbers, P2 and P1, which are both "large" (a relative term, the definition of which continues to move forward as computing power increases). We then multiply these two primes to produce the product, N. The difficulty arises when, being given

N, we try and find the original P1 and P2. The **Rivest-Shamir-Adleman** public key infrastructure encryption protocol is one of many based on this problem. To simplify matters to a great degree, the N product is the **public key** and the P1 and P2 numbers are, together, the **private key**.

This problem is one of the most fundamental of all mathematical concepts. It has been studied intensely for the past 20 years and the consensus seems to be that there is some unproven or undiscovered law of mathematics that forbids any shortcuts. That said, the mere fact that it is being studied intensely leads many others to worry that, somehow, a breakthrough may be discovered.

The Elliptic Curve Discrete Logarithm Problem: This is a new cryptographic protocol based upon a reasonably well-known mathematical problem. The properties of elliptic curves have been well known for centuries, but it is only recently that their application to the field of cryptography has been undertaken.

First, imagine a huge piece of paper on which is printed a series of vertical and horizontal lines. Each line represents an integer with the vertical lines forming x class components and horizontal lines forming the y class components. The intersection of a horizontal and vertical line gives a set of coordinates (x,y). In the highly simplified example below, we have an elliptic curve that is defined by the equation:

$$y^2 + y = x^3 \cdot x^2 \text{ (this is way too small for use in a real life application, but it will illustrate the general idea)}$$

For the above, given a definable operator, we can determine any third point on the curve given any two other points. This definable operator forms a "group" of finite length. To add two points on an elliptic curve, we first need to understand that any straight line that passes through this curve intersects it at precisely three points. Now, say we define two of these points as u and v: we can then draw a straight line through two of these points to find another intersecting point, at w. We can then draw a vertical line through w to find the final intersecting point at x. Now, we can see that $u + v = x$. This rule works, when we define another imaginary point, the Origin, or O, which exists at (theoretically) extreme points on the curve. As strange as this problem may seem, it does permit for an effective encryption system, but it does have its detractors.

On the positive side, the problem appears to be quite intractable, requiring a shorter key length (thus allowing for quicker processing time) for equivalent security levels as compared to the Integer Factorization Problem and the Discrete Logarithm Problem. On the negative side, critics contend that this problem, since it has only recently begun to be implemented in cryptography, has not had the intense scrutiny of many years that is required to give it a sufficient level of trust as being secure.

This leads us to more general problem of cryptology than of the intractability of the various mathematical concepts, which is that the more time, effort, and resources that can be

devoted to studying a problem, then the greater the possibility that a solution, or at least a weakness, will be found.

cryptoperiod

A cryptoperiod (sometimes called a *key lifetime* or a *validity period*) is a specific time span during which a cryptographic **key** is authorized, or for which a key setting remains in effect. A key uses an **algorithm** to create **ciphertext** from **plaintext** (ordinary unencrypted text). The cryptoperiod is decided by weighing factors such as the sensitivity of the encrypted data, the risk of key compromise, and the cost of **rekeying** (encrypting the same material with a new key). Throughout the cryptoperiod, a key can be used to verify or decrypt data. The effective use of cryptoperiods is an important part of key management.

A cryptoperiod is usually expressed as a span of calendar or clock time, but may also be expressed as a maximum volume of data to be encrypted by an algorithm for a particular key. The span of some cryptoperiods can be a number of decades since keys may sometimes be archived for a very long time.

Crystal Reports

Crystal Reports is a popular Windows-based report writer (report generation program) that allows a programmer to create reports from a variety of data sources with a minimum of written code. Developed by Seagate Software, Crystal Reports can access data from most widely-used databases and can integrate data from multiple databases within one report using Open Database Connectivity (ODBC).

Crystal Reports uses an **ActiveX control** called CrystalReport to establish a connection with another program. A programmer can set properties of the CrystalReport control during design time or at run time.

The programmer can use automation tools called Experts to be guided through common tasks, such as linking and embedding reports. Crystal Reports treats all text, graphics, and database fields as **objects** that a programmer can place, arrange, and format on forms. The program also generates a recordset object and code needed to perform programming tasks such as **loops** or mathematical calculations.

Crystal Reports can create a report **on the fly** from user-defined variables and can convert it to HTML and publish it to the Web automatically.

CSU/DSU

A CSU/DSU (Channel Service Unit/Data Service Unit) is a hardware device about the size of an external **modem** that converts a digital data **frame** from the communications technology used on a local area network (LAN) into a frame appropriate to a wide-area network (WAN) and vice versa. For example, if you have a Web business from your own home and have leased a digital line (perhaps a **T-1** or fractional T-1 line) to a phone company or a **gateway** at an Internet service provider, you have a CSU/DSU at your end and the phone company or **gateway** host has a CSU/DSU at its end.

The Channel Service Unit (CSU) receives and transmits signals from and to the WAN line and provides a barrier for electrical interference from either side of the unit. The CSU can also echo **loopback** signals from the phone company for testing purposes. The Data Service Unit (DSU) manages line control, and converts input and output between **RS-232C**, **RS-449**, or **V.xx** frames from the LAN and the time-division multiplexed (**TDM**) DSX frames on the T-1 line. The DSU manages timing errors and signal regeneration. The DSU provides a modem-like interface between the computer as Data Terminal Equipment (**DTE**) and the CSU.

CSU/DSUs are made as separate products or are sometimes part of a T-1 WAN card. A CSU/DSU's Data Terminal Equipment interface is usually compatible with the **V.xx** and **RS-232C** or similar serial interface. Manufacturers of separate unit or integrated CSU/DSUs include Adtran, Cisco, and Memotec.

The CSU originated at AT&T as an interface to their nonswitched digital data system. The DSU provides an interface to the data terminal equipment (DTE) using a standard (EIA/CCITT) interface. It also provides testing capabilities.

CSV

See "comma-separated values file"

CTD

See "cumulative trauma disorder"

CTI

CTI (computer-telephony integration), or sometimes simply "computer telephony," is the use of computers to manage telephone calls. The term is used in describing the

computerized services of **call centers**, such as those that direct your phone call to the right department at a business you're calling. It's also sometimes used to describe the ability to use your personal computer to initiate and manage phone calls (in which case you can think of your computer as your personal call center).

CTI applications provide the ability to do one or more of the following:

- Authenticate callers. Using one of several standard methods, the telephone number of the caller can be screened against a database.
- Recognize a voice, either for authentication or for message forwarding
- Using live, recorded voice, or touch-tone entered input, determine how to process a call (for example, by forwarding it to the appropriate person or department)
- Provide interactive voice response (IVR) to callers
- Match the number of a caller with a customer record and display it for reference when talking to the caller
- Manage voice or video conferences
- Collect and display pending live calls or messages that have been left by callers
- Receive fax messages and route them to appropriate fax machines
- For outbound calling such as telemarketing, predial callers
- Based on call input, initiate a smart agent application to provide help with the caller's request

The Advanced Intelligent Network (**AIN**) is a telephone service **architecture** that separates CTI services from call switching and will make it easier to add new services. The Windows Telephony Application Program Interface (**TAPI**) and Novell's TSAPI are programming interfaces intended to make it easier to create applications that enable telephone services on a personal computer or in a local area network.

CTR

See "clickthrough rate"

cubic meter

The cubic meter, also called the meter cubed, is the unit of **volume** in the International System of Units. The symbol for cubic meters is m^3 . Less formally, cubic meter is sometimes abbreviated cu m.

When calculating volume, it is important to realize that volume is proportional to the cube of the linear dimension. Thus, if all linear dimensions are doubled, the volume becomes eight times (2^3) as great; if all linear dimensions are cut to $1/3$, the volume becomes $1/27$ ($(1/3)^3$) as great. A volume of $1 m^3$ is equal to 1,000,000 centimeters cubed ($10^6 cm^3$)

or 1,000,000,000 millimeters cubed ($10^9 mm^3$). In the opposite sense, $1 m^3$ is equal to 0.000000001 kilometer cubed ($10^{-9} km^3$).

When converting between cubic meters and non-SI units of volume such as cubic inches (cu in) or cubic miles (cu mi), the linear-unit conversion factor must be cubed. For example, one meter is approximately 39.37 inches (39.37 in); therefore $1 m^3 = 39.37^3 = 6.102 \times 10^4$ cu in (approximately). As another example, 1 meter is about 0.0006215 mile (6.215×10^{-4} mi); therefore $1 m^3 = (6.215 \times 10^{-4})^3 = 2.401 \times 10^{-10}$ cu mi (approximately).

Also see **meter**, **square meter**, and International System of Units (SI).

cuckoo egg

A cuckoo egg is an **MP3** file that typically contains 30 seconds of the original song with the remainder of the song overwritten with cuckoo clock noises, **white noise**, and/or voice messages such as, "Congratulations, you must've goofed up somewhere." Ideally, a cuckoo egg should have the same playing length as the music it pretends to be. The purpose of cuckoo eggs is to deter the **downloading** and sharing of MP3 files using **Napster** and similar approaches.

Typically, a Napster user downloads an MP3 file and sometimes share it with others before listening to it. Recognizing this, a cuckoo egg creator creates the cuckoo egg to look exactly like a real MP3 file. The user then unknowingly shares the cuckoo egg with other unsuspecting users spreading the cuckoo egg like a virus. Unlike a virus, cuckoo eggs do not damage computers, but simply annoy and waste the time of those who download the files.

The Cuckoo Egg Project began with Michael and Stephanie Fix. Stephanie Fix is a musician who is concerned about the illegal availability of copyrighted music through Napster. The concept centers on the idea of how a real cuckoo bird lays its eggs in another bird's nest. To the Fixes, the Napster system is like a huge nest of MP3 files, a perfect environment in which to lay cuckoo eggs

The first cuckoo egg was laid on June 10, 2000. Since then, Napster users have posted hundreds of angry messages at the Cuckoo Egg Project's Web site. Whether it's deterring them from downloading other songs has not been determined.

There is an ironic twist to the Cuckoo Egg Project. According to the official Web site's **FAQ**, cuckoo eggs are also not legal, because they also use unauthorized portions of copyrighted songs. But they claim that only a sample portion is used compared to the entire song being used with Napster, which is more defensible according to fair use laws. Anyone who creates and distributes MP3 files can create cuckoo eggs.

CUL

See "chat abbreviations"

cumulative trauma disorder

In information technology, cumulative trauma disorder (CTD) refers to any of several physical problems that can result from improper or excessive use of a computer display or terminal. Other terms for repetitive stress disorders are *repetitive stress injury (RSI)* and *repetitive motion disorder (RMD)*.

Perhaps the most well-known CTD is *carpal tunnel syndrome*. In occupations involving long hours of keyboard use over a period of years, the tissue in the wrist can become chronically inflamed and swollen. In severe cases, scarring occurs. The main nerve leading from the arm into the hand becomes pinched. The result is arthritis-like pain and stiffness in the hand and fingers. If not treated, the condition can progress until keyboard use becomes impossible. Proper hand positioning, and the use of wrist supports, can minimize the risk that a computer user will develop this syndrome.

Poor posture, caused by improper chair height, a desk that is too high or low, or a display too far below eye level, can bring about back pain and spasms. In severe cases, the condition can be disabling, and its cause can be mistaken for an organic illness such as kidney disease. Pain and stiffness may also occur in the legs, neck, and shoulders. The problem can usually be corrected by paying careful attention to **ergonomic** aspects of the computer or workstation.

Any type of close-range work over a period of years can cause nearsightedness. Poor lighting, improper display adjustment, or the use of excessively small fonts and/or graphics can result in eye strain, often attended by chronic headaches that can be mistaken for migraines.

current

Also see **voltage**, **resistance**, and **Ohm's Law**.

Current is a flow of electrical charge carriers, usually electrons or electron-deficient atoms. The common symbol for current is the uppercase letter I. The standard unit is the **ampere**, symbolized by A. One ampere of current represents one coulomb of electrical charge (6.24×10^{18} charge carriers) moving past a specific point in one second. Physicists consider current to flow from relatively positive points to relatively negative points; this is called conventional current or Franklin current. Electrons, the most common charge carriers, are negatively charged. They flow from relatively negative points to relatively positive points.

Electric current can be either direct or alternating. Direct current (**DC**) flows in the same direction at all points in time, although the instantaneous magnitude of the current might vary. In an alternating current (**AC**), the flow of charge carriers reverses direction periodically. The number of complete AC cycles per second is the **frequency**, which is measured in **hertz**. An example of pure DC is the current

produced by an electrochemical cell. The output of a power-supply rectifier, prior to filtering, is an example of pulsating DC. The output of common utility outlets is AC.

Current per unit cross-sectional area is known as *current density*. It is expressed in amperes per square meter, amperes per square centimeter, or amperes per square millimeter. Current density can also be expressed in amperes per circular mil. In general, the greater the current in a conductor, the higher the current density. However, in some situations, current density varies in different parts of an electrical conductor. A classic example is the so-called *skin effect*, in which current density is high near the outer surface of a conductor, and low near the center. This effect occurs with alternating currents at high frequencies. Another example is the current inside an active electronic component such as a field-effect transistor (**FET**).

An electric current always produces a **magnetic field**. The stronger the current, the more intense the magnetic field. A pulsating DC, or an AC, characteristically produces an **electromagnetic field**. This is the principle by which **wireless** signal propagation occurs.

curses

In C programming, curses is a collection of precompiled **routines** stored as **objects** for text-based terminals that is used to create similarity of function. Curses probably gets its name from its purpose of providing a common user interface for terminal-specific initiation of cursor movement.

Terminals frequently use different ways to initiate particular cursor movements. For example, to make the cursor move up a line, a VT100 terminal has to send the characters "Esc," "]" and "A," while a Televideo 920C terminal has to send "CTRL-K." This could get terribly complicated if programmers had to write separate versions for every terminal. Another problem is that the same tasks would have to be redone every time a program that depended on cursor action was written. The curses library contains **functions** that a program calls to send the desired cursor action characters. The program doesn't have to contain information about the proper characters but just uses a simple-to-understand syntax (e.g.: "clear()" will clear the screen).

Curses hides the particular screen details of different terminals from the programmer, who sees a display containing multiple non-overlapping windows. Window contents can be changed in a fairly straight-forward manner and the curses library will be behind the scenes, working away doing whatever is necessary to get the desired message through—with the least possible stress to the programmer.

cursor

A cursor is the position indicator on a computer **display screen** where a user can enter **text**. In an **operating system** with a graphical user interface (**GUI**), the cursor is also a visible and moving pointer that the user controls with a **mouse**, **touch pad**, or similar input device. The user uses the pointing cursor and special input buttons to establish where the position indicator cursor will be or to select a particular program to run or file to view. Typically, the pointing cursor is an arrow and the text entry position cursor is a blinking underscore or vertical bar. Most operating systems allow the user to choose another appearance for the cursor.

In the Windows operating system, the pointing cursor turns into a pointing hand when it is pointed to a specific object and into an hourglass while the system is starting a requested program.

CUseeMe

CUseeMe is a low-cost product for Internet videoconferencing. Each user installs the CUseeMe software and, assuming they have an Internet connection, can then have person-to-person or group discussions. A "whiteboard" allows users to exchange messages and collaborate. Users can also chat online. Users with a small attached video camera (optional) can transmit their picture to other users in a conference.

Customer Information Control System

See "CICS"

customer life cycle

In customer relationship management (**CRM**), customer life cycle is a term used to describe the progression of steps a customer goes through when considering, purchasing, using, and maintaining loyalty to a product or service. Marketing analysts Jim Sterne and Matt Cutler have developed a matrix that breaks the customer life cycle into five distinct steps: reach, acquisition, conversion, retention, and loyalty. In layman's terms, this means getting a potential customer's attention, teaching them what you have to offer, turning them into a paying customer, and then keeping them as a loyal customer whose satisfaction with the product or service urges other customers to join the cycle. The customer life cycle is often depicted by an ellipse, representing the fact that customer retention truly is a cycle and the goal of effective CRM is to get the customer to move through the cycle again and again.

customer premises equipment

Customer premises equipment (CPE) is telephone or other service provider equipment that is located on the customer's premises (physical location) rather than on the provider's premises or in between. Telephone handsets, cable TV

set-top boxes, and **Digital Subscriber Line** routers are examples. Historically, this term referred to equipment placed at the customer's end of the telephone line and usually owned by the telephone company. Today, almost any end-user equipment can be called customer premise equipment and it can be owned by the customer or by the provider.

Customer Proprietary Network Information

See "CPNI"

customer relationship analysis

Customer relationship analysis (CRA), sometimes termed *customer relationship analytics*, is the processing of data about customers and their relationship with the enterprise in order to improve the enterprise's future sales and service and lower cost. This term is generally a synonym for **CRM analytics**.

Customer relationship analysis can be considered a form of online analytical processing (**OLAP**) and may employ **data mining**. As Web sites have added a new and often faster way to interact with customers, the opportunity and the need to turn data collected about customers into useful information has become generally apparent. As a result, a number of software companies have developed products that do customer data analysis.

According to an article in *InfoWorld*, customer relationship analysis can provide customer segmentation groupings (for example, at its simplest, dividing customers into those most and least likely to repurchase a product); profitability analysis (which customers lead to the most profit over time); personalization (the ability to market to individual customers based on the data collected about them); event monitoring (for example, when a customer reaches a certain dollar volume of purchases); what-if scenarios (how likely is a customer or customer category that bought one product to buy a similar one); and predictive modeling (for example, comparing various product development plans in terms of likely future success given the customer knowledge base). Data collection and analysis are viewed as a continuing and iterative process and ideally over time business decisions are refined based on feedback from earlier analysis and consequent decisions.

Benefits of customer relationship analysis are said to lead not only to better and more productive customer relations in terms of sales and service but also to improvement in **supply chain management** (lower inventory and speedier delivery) and thus lower costs and more competitive pricing.

One of the major challenges implicit in customer relationship analysis is how to integrate the analytical software with existing **legacy** systems as well as with other new systems.

A new area of application and data collection has to do with Web site customer usage.

customer relationship management

CRM (customer relationship management) is an information industry term for methodologies, software, and usually Internet capabilities that help an **enterprise** manage customer relationships in an organized way. For example, an enterprise might build a **database** about its customers that described relationships in sufficient detail so that management, salespeople, people providing service, and perhaps the customer directly could access information, match customer needs with product plans and offerings, remind customers of service requirements, know what other products a customer had purchased, and so forth.

According to one industry view, CRM consists of:

- Helping an enterprise to enable its marketing departments to identify and target their best customers, manage marketing campaigns with clear goals and objectives, and generate quality leads for the sales team.
- Assisting the organization to improve telesales, account, and sales management by optimizing information shared by multiple employees, and streamlining existing processes (for example, taking orders using mobile devices).
- Allowing the formation of individualized relationships with customers, with the aim of improving customer satisfaction and maximizing profits; identifying the most profitable customers and providing them the highest level of service.
- Providing employees with the information and processes necessary to know their customers, understand their needs, and effectively build relationships between the company, its customer base, and distribution partners.

customer valuation

In customer relationship management (CRM), customer valuation is a scoring process used to help a company determine which customers the company should target in order to maximize profit. Customer valuation requires that the company evaluate past data to learn which customers purchased recently, which customers purchased frequently, and which customers spent the most money, in hopes that the company can forecast future purchase potential and make sure time and resources are spent only on its best customers.

To understand how customer valuation works, let's imagine there is a company that manufactures skateboards called CoolSkate. CoolSkate's sales are made primarily through Internet and print catalog sales. Through surveys and questionnaires on their Web site, CoolSkate has accumulated quite a bit of data about the buying habits, preferences, and age range of their customers. With this data, CoolSkate will

devise a customer valuation scoring system that awards points based on total purchasing dollars, repeat purchases, and customer loyalty. CoolSkate can then use the information gained from the customer valuation scores to predict repeat-purchase probability as well as the probability of attrition, and target their promotions to customers who are likely to make new purchases.

Customer valuation is based upon the 80/20 rule in marketing, whereby a company spends the majority of its time working with its best customers. There are many software applications on the market to help companies determine a point system relevant to their products or services and combine aggregated data to determine customer valuation.

customer-facing

Customer-facing is an adjective used to describe a hardware or software product, technology, or anything that the customer of a business deals with directly. This can include the **user interface** of a software application, the **help desk** that a customer can phone into, any mailing or other contact that a customer receives, or policies that describe how to interact with customers (since the customer will experience the effect of these policies).

Since both customers and companies perceive value in a company's keeping track of and anticipating customer needs, customer-facing software is now sold for the purpose of **customer relationship management**.

CUT

See "Coordinated Universal Time"

cut-and-paste attack

A cut-and-paste attack is an assault on the **integrity** of a security system in which the attacker substitutes a section of **ciphertext** (encrypted text) with a different section that looks like (but is not the same as) the one removed. The substituted section appears to decrypt normally, along with the authentic sections, but results in **plaintext** (unencrypted text) that serves a particular purpose for the attacker. Essentially, the attacker cuts one or more sections from the ciphertext and reassembles these sections so that the decrypted data will result in coherent but invalid information. Cut-and-paste is a type of *message modification* attack: the attacker removes a message from network traffic, alters it, and reinserts it. This is called an *active attack*, because it involves an attempts to change information; in comparison, a *passive attack*, such as **password sniffing**, seeks information but does not itself modify the valid information, although it may be used in conjunction with an active form of attack for various purposes.

When the data modified in the attack involves critical enterprise or personal information, the cut-and-paste attack can pose a serious threat to security. A typical use for a

cut-and-paste attack is the modification of information on a customer order form for the purchase of goods or services over the Web. The attacker modifies the form so that the victim's credit card number is sent to the vendor but other information—such as the attacker's chosen delivery address and the type or quantity of goods ordered—is “pasted” into the form which the customer's valid information has been “cut.” The apparently unaltered form, assembled from a “cut-and-pasted” combination of valid and invalid data, is submitted to the vendor.

CVO

See “Chief Visionary Officer”

CVS

See “Concurrent Versions System”

cyber

“Cyber” is a prefix used to describe a person, thing, or idea as part of the computer and information age. Taken from *kybernetes*, Greek for “steersman” or “governor,” it was first used in **cybernetics**, a word coined by Norbert Wiener and his colleagues. Common usages include cyberculture, **cyberpunk**, and **cyberspace**.

cybercafe

A cybercafe is a cafe, coffee or espresso shop, or similar food and/or beverage-serving place that has a number of personal computers connected to the Internet and available for use by customers. Some cybercafes allow customers to use the computers at no charge; others charge by the hour or fraction of an hour. In September, 1997, there were estimated to be more than 1,000 cybercafes internationally. By 2001, there were perhaps tens of thousands, with at least one in almost every small community in many countries. In cities such as Beijing, China; Kathmandu, Nepal; and Florence, Italy, there are now chains of cybercafes.

If you travel and need access to the Internet, a cybercafe might be one solution. Call ahead and find out location and hours. If possible, reserve a computer at a certain time.

cybercitizen

The term “cybercitizen” denotes a “citizen of the Internet” or a member of the “cybercommunity.”

Netizen has the same meaning.

cybercommuting

See “telecommuting”

cybernetics

Cybernetics is a word coined by group of scientists led by Norbert Wiener and made popular by Wiener's book of 1948, *Cybernetics or Control and Communication in the Animal and the Machine*. Based on the Greek “kybernetes,” meaning steersman or governor, cybernetics is the science or study of control or regulation mechanisms in human and machine systems, including computers.

cyberpicketing

Cyberpicketing is the use of the Internet to protest a corporation or other institution's wages, work conditions, products, environmental policy, or other issues. The most common type of cyberpicketing is **e-mail** directed to CEOs or other influential parties. Cyberpicketing can also involve setting up and maintaining a **Web site** as a way to publicize and organize action. In some cases, cyberpicketing sites have been designed to look like and have **domain names** similar to the Web site of the institution that is being picketed against.

cyberprise

A cyberprise is a Web-enabled enterprise. The word combines the ideas of **cyberspace** and **enterprise** so well that a company named Wall Data has trademarked it. Wall Data's Cyberprise (™) products, which include a Web server, a **database** manager for Web pages, and a Web page publisher, are aimed at allowing an enterprise to quickly get new and existing information on their public Web site or on an **intranet** or **extranet**.

cyberpunk

Cyberpunk is a sensibility or belief that a few outsiders, armed with their own individuality and technological capability, can fend off the tendencies of traditional institutions to use technology to control society. The term, combining “**cyber**” and punk, possibly originated in 1980 with Bruce Bethke's short story, “Cyberpunk.” An editor of Isaac Asimov's Science Fiction Magazine, Gardner Dozois, is credited with associating the word with a literary movement that includes the science fiction of William Gibson and Neal Stephenson.

The alt.cyberpunk.FAQ lists several categories of groups associated with cyberpunk:

- **hacker**, who represent the best kind of cyberpunk
- **cracker**, who attempt to break into computer systems
- **phreak**, who attempt to break into telephone systems
- **Cypher-punks**, who attempt to break codes and foil security systems

Additional groups include “transhumans,” who attempt to exploit technology to increase life expectancy and human potential and “extropians,” a kind of libertarian group that believes in something called “spontaneous order.” The writer of the alt.cyberpunk.FAQ indicates that some people believe cyberpunk to be (intrinsically) undefinable and that anyone claiming to be a “cyberpunk” will likely be laughed off their Usenet newsgroup.

cyberspace

Cyberspace has been defined as “the total interconnectedness of human beings through computers and telecommunication without regard to physical geography.”

William Gibson is sometimes credited with inventing or popularizing the term by using it in his novel of 1984, *Neuromancer*.

cybersquatting

Cybersquatting is reserving an Internet **domain name** (often referred to as a “dot com” name) for the purpose of selling it later to a company that wants to use it. Commercial domain names (technically, you reserve a **second-level domain name**) are obtained from one of several registries, companies authorized to ensure that a domain name you want is unique (no one else already has it) and issue it to you if it is. However, these registries make no attempt to determine whether the domain name is one that rightfully ought to go to someone else. The principle is “First come, first served.” For this reason, a number of enterprising individuals and companies have applied for and reserved domain names that they think someone else will want, either now or in the future. Well-known companies or their products, sports figures and other celebrities, political candidates, and others often discover that someone else has already reserved the domain name (for example, “sammysosa.com”) they would most likely want to use. Although trademark laws may offer some protection, it is often cheaper to buy the domain name from the cybersquatter than it is to sue for its use.

Many cybersquatters reserve common English words, reasoning that sooner or later someone will want to use one for their Web site. Examples of words sold by cybersquatters to companies developing significant Web sites include drugstore.com, furniture.com, gardening.com, and Internet.com. eBay, the auction site, sometimes lists domain names for sale. Several cybersquatter companies offer their wares at their own Web sites.

Since there is an initial and yearly fee for owning a domain name, some cybersquatters reserve a long list of names and defer paying for them until forced to—preempting their use by others at no cost to themselves. The registry companies are working on this problem. Meanwhile, the Internet Corporation for Assigned Names and Numbers (ICANN),

which licenses the domain name registrars, is working on a process for resolving domain name disagreements outside of the regular court system.

The term derives from *squatting*, the practice of building some kind of home or dwelling or in some way using someone else’s landed property without their permission.

cyborg

Cyborg, a compound word derived from **cybernetics** and **organism**, is a term coined by Manfred Clynes in 1960 to describe the need for mankind to artificially enhance biological functions in order to survive in the hostile environment of Space. Originally, a cyborg referred to a human being with bodily functions aided or controlled by technological devices, such as an oxygen tank, artificial heart valve or insulin pump. Over the years, the term has acquired a more general meaning, describing the dependence of human beings on technology. In this sense, cyborg can be used to characterize anyone who relies on a computer to complete their daily work.

cybrarian

A cybrarian (pronounced sai-BREHR-i-uhn, a compound of **cyber** and **librarian**) is a library and information science professional that specializes in using the Internet as a resource tool. The term has gained currency among many librarians who use the Internet. The American Library Association hosts a section called Cyberlib.net, written by Pat Sensor, author of *The Cybrarian’s Manual*.

cycle time

Cycle time is the time, usually measured in **nanoseconds**, between the start of one random access memory (**RAM**) access to the time when the next access can be started. **Access time** is sometimes used as a synonym (although IBM deprecates it). Cycle time consists of **latency** (the overhead of finding the right place for the memory access and preparing to access it) and transfer time.

Cycle time should not be confused with processor *clock cycles* or **clock speed**, which have to do with the number of cycles per second (in megahertz or **MHz**) to which a processor is paced.

cycles per second

Cps (cycles per second) is the measure of how frequently an **alternating current** changes direction. This term has been replaced by the term **hertz** (Hz).

cyclic redundancy checking

Cyclic redundancy checking is a method of checking for errors in data that has been transmitted on a communications link. A sending device applies a 16- or 32-bit **polynomial** to a block of data that is to be transmitted

#

A

B

C

D

E

J

K

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

and appends the resulting cyclic redundancy code (CRC) to the block. The receiving end applies the same polynomial to the data and compares its result with the result appended by the sender. If they agree, the data has been received successfully. If not, the sender can be notified to resend the block of data.

The **ITU-TS** (CCITT) has a standard for a 16-bit polynomial to be used to obtain the cyclic redundancy code (CRC) that is appended. IBM's **Synchronous Data Link Control** and other protocols use CRC-16, another 16-bit polynomial. A 16-bit cyclic redundancy code detects all single and double-bit errors and ensures detection of 99.998% of all possible errors. This level of detection assurance is considered sufficient for data transmission blocks of 4 kilobytes or less. For larger transmissions, a 32-bit CRC is used. The **Ethernet** and **token ring** local area network protocols both used a 32-bit CRC.

A less complicated but less capable error detection method is the **checksum** method. See **modem error-correcting protocols** for a list of protocols that use either of these methods.

Cyrix

Cyrix (pronounced SYE-rihks) was a line of low-cost microprocessors intended for personal computers and information appliances that competed, along with **AMD** and **Intel**, for the low-cost **microprocessor** market. Acquired by VIA Technologies, a Taiwan supplier of chipsets and processors, the Cyrix technology continues to be offered in the VIA Cyrix MII processor. VIA also offers its own VIA C3 processor.

D

DAC

See “digital-to-analog conversion”

daemon

A daemon (pronounced DEE-muhn) is a program that runs continuously and exists for the purpose of handling periodic service requests that a computer system expects to receive. The daemon program forwards the requests to other programs (or processes) as appropriate. Each server of pages on the Web has an *HTTPD* or **Hypertext Transfer Protocol** daemon that continually waits for requests to come in from Web clients and their users.

In mythology, a daemon, according to Webster’s, was “an attendant power or spirit.”

Daemon can be confused with **demon**, which has a different but similar meaning. *The New Hacker’s Dictionary* says that a daemon is a program that runs by itself directly under the operating system whereas a demon is part of a larger application program.

DAML

DAML (DARPA Agent Markup Language) is a **markup** language for the U.S. Defense Advanced Research Project Agency (**DARPA**) that is based on the Extensible Markup Language (**XML**). DAML is designed to have a greater capacity than XML for describing objects and the relationships between objects, to express **semantics**, and to create a higher level of **interoperability** among Web sites. As the central research and development agency for the U. S. Department of Defense, DARPA was instrumental in the creation of the **Internet** and many of its technologies. DARPA is developing DAML as a technology with intelligence built into the language through the behaviors of **agents**, programs that can dynamically identify and comprehend sources of information, and interact with other agents in an autonomous fashion.

DAML agents can be embedded in code and maintain awareness of their environment, are user-directed, but have the capacity to behave autonomously. They also have the capacity to “learn” from experience, so that they improve their behavior over time. DAML uses a number of different types of agents (such as *information agents*, *event monitoring agents*, and *secure agents*) for different purposes. DAML’s semantic knowledge and autonomous behavior is expected to make it capable of processing large volumes of data much as a human being would process it. DAML includes a type of **query** language with a specialized ability to find and process relevant information—for example, finding related information on separate Web sites and processing it into a comprehensive report.

D-AMPS

D-AMPS is now called **Time Division Multiple Access/IS-136**.

D-AMPS (Digital-Advanced Mobile Phone Service), sometimes spelled DAMPS, is a **digital** version of AMPS (**Advanced Mobile Phone Service**), the original **analog** standard for **cellular telephone** phone service in the U.S. Both D-AMPS and AMPS are now used in many countries. D-AMPS adds time division multiple access (**TDMA**) to AMPS to get three channels for each AMPS channel, tripling the number of calls that can be handled on a channel. D-AMPS is Interim Standard-136 from the Electronics Industries Association/Telecommunication Industries Association (EIA/TIA).

Like AMPS, D-AMPS uses frequency ranges within the 800 and 900 megahertz (**MHz**) **electromagnetic radiation spectrum**. Each service provider can use half of the 824-849 MHz range for receiving signals from cellular phones and half the 869-894 MHz range for transmitting to cellular phones. The bands are divided into 30 **kHz** sub-bands, called *channels*. The receiving channels are called *reverse channels* and the sending channels are called *forward channels*. The division of the spectrum into sub-band channels is achieved by using frequency division multiple access (**FDMA**). The time division multiple access processing (**TDMA**) is added to each sub-band channel created with FDMA to triple the number of channels available.

Although AMPS and D-AMPS originated for the North American cellular telephone market, they are now used worldwide with over 74 million subscribers, according to Ericsson, one of the major cellular phone manufacturers. D-AMPS is one of three digital wireless technologies that use TDMA. The other two are **GSM** and **PDC**. Each of these technologies interprets TDMA differently so they are not compatible. An advantage of D-AMPS is that it is easier to upgrade to from an existing analog AMPS network. An alternative to D-AMPS and the other two TDMA technologies is direct sequence code division multiple access (**CDMA**).

DAO

DAO (Data Access Objects) is an application program interface (**API**) available with Microsoft’s Visual Basic that lets a programmer request access to a Microsoft Access **database**. DAO was Microsoft’s first object-oriented interface with databases. DAO objects **encapsulate** Access’s Jet functions. Through Jet functions, it can also access other Structured Query Language (**SQL**) databases.

To conform with Microsoft's vision of a Universal Data Access (UDA) model, programmers are being encouraged to move from DAO, although still widely used, to ActiveX Data Objects (ADO) and its low-level interface with databases, OLE DB. ADO and OLE DB offer a faster interface that is also easier to program.

dark fiber

Dark fiber is **optical fiber** infrastructure (cabling and **repeaters**) that is currently in place but is not being used. Optical fiber conveys information in the form of light pulses so the "dark" means no light pulses are being sent. For example, some electric utilities have installed optical fiber cable where they already have power lines installed in the expectation that they can lease the infrastructure to telephone or cable TV companies or use it to interconnect their own offices. To the extent that these installations are unused, they are described as dark.

"Dark fiber service" is service provided by local exchange carriers (LECs) for the maintenance of optical fiber transmission capacity between customer locations in which the light for the fiber is provided by the customer rather than the LEC.

DARPA Agent Markup Language

See "DAML"

DARPA

DARPA (Defense Advanced Research Projects Agency) is the independent research branch of the U.S. Department of Defense that, among its other accomplishments, was the funder of a project that in time was to lead to the creation of the **Internet**. Originally called ARPA (the "D" was added to its name later), DARPA came into being in 1958 as a reaction to the success of Sputnik, Russia's first manned satellite. DARPA's explicit mission was (and still is) to think independently of the rest of the military and to respond quickly and innovatively to national defense challenges.

In the late 1960s, DARPA provided funds and oversight for a project aimed at interconnecting computers at four university research sites. By 1972, this initial network, now called the ARPANet, had grown to 37 computers. ARPANet and the technologies that went into it, including the evolving Internet Protocol (IP) and the Transmission Control Protocol (TCP), led to the Internet that we know today.

DARPA Net

DARPA Net originated in 1969 when the Defense Advanced Research Projects Agency, a part of the U.S. Defense Department, recognized a need for an efficient way to exchange military information between scientists and researchers based in different geographic locations.

DARPA Net originally consisted of a four-computer network. By 1972, it had grown to a network of 37 computers and was renamed **ARPANet**. ARPANet led to today's **Internet**.

DASD

DASD, pronounced DAZ-dee (direct access storage device), is a general term for magnetic disk **storage** devices that have historically been used in the **mainframe** and **minicomputer** (mid-range computer) environments. When used, it may also include **hard disk** drives for personal computers. A recent form of DASD is the *redundant array of independent disks* (**RAID**).

The "direct access" means that all data can be accessed directly in about the same amount of time rather than having to progress sequentially through the data.

DAT

DAT (Digital Audio Tape) is a standard medium and technology for the **digital** recording of **audio** on tape at a professional level of quality. A DAT drive is a digital tape recorder with rotating heads similar to those found in a video deck. Most DAT drives can record at **sample rates** of 44.1 KHz, the CD audio standard, and 48 KHz. DAT has become the standard archiving technology in professional and semi-professional recording environments for master recordings. Digital inputs and outputs on professional DAT decks allow the user to transfer recordings from the DAT tape to an audio workstation for precise editing. The compact size and low cost of the DAT medium makes it an excellent way to compile the recordings that are going to be used to create a CD master.

As an archiving medium, DAT is an alternative to consider along with:

- Digital Data Storage (DDS1 through DDS3)
- Optical disk
- VHS tape

data

1) In computing, data is **information** that has been translated into a form that is more convenient to move or process. Relative to today's **computers** and transmission media, data is information converted into **binary digital** form.

2) In computer component interconnection and network communication, data is often distinguished from "control information," "control bits," and similar terms to identify the main content of a transmission unit.

3) In telecommunications, data sometimes means **digital**-encoded information to distinguish it from **analog**-encoded information such as conventional telephone voice calls. In general, "analog" or voice transmission requires a dedicated continual connection for the duration of a related series of

transmissions. Data transmission can often be sent with intermittent connections in **packets** that arrive in piecemeal fashion.

4) Generally and in science, data is a gathered body of facts.

Some authorities and publishers, cognizant of the word's Latin origin and as the plural form of "datum," use plural verb forms with "data." Others take the view that since "datum" is rarely used, it is more natural to treat "data" as a singular form.

Data Access Arrangement

A Data Access Arrangement (DAA) is an electronic interface within a computer and its **modem** to a public telephone line. A DAA is also sometimes called a Telephone Line Interface Circuit (or Module). DAAs are required in any device that attaches to the public switched telephone network (PSTN), including **fax machines**, **private branch exchange**, **set-top box**, and alarm systems. Among other things, the DAA isolates the electronic device from the higher voltage on the telephone line. DAA circuitry requires registration with the telephone system governing authority (such as the Federal Communications Commission in the U. S.). However, most manufacturers of modems and other devices build an already-approved DAA design into the modem.

A Data Access Arrangement can be built into a computer's motherboard but is more commonly built into the modem.

Data Access Objects

See "DAO"

data aggregation

Data aggregation is any process in which information is gathered and expressed in a summary form, for purposes such as statistical analysis. For example, the Web site of a music club might collect aggregate data about music searches, and analyze the resultant data to inform the music club owners about the most frequently requested artists and CDs. A common aggregation purpose is to get more information about particular groups, based on any specific variables, such as age, profession, or income. The information about such groups can then be used for Web site **personalization**, to choose content and advertising likely to appeal to an individual belonging to one or more groups for which data has been collected. For example, a music club might advertise certain music based on the age of the user and the data aggregate for their age group. Online analytic processing (OLAP) is a simple type of data aggregation in which the marketer uses an online reporting mechanism to process the information.

Data aggregation can be user-based: Personal data aggregation services offer the user a single point for collection of their personal information from other Web sites. The customer uses a single master personal identification

number (PIN) to give them access to their various accounts (such as those for financial institutions, airlines, book and music clubs, and so on). Performing this type of data aggregation is sometimes referred to as "screen scraping."

data analysis

See "data mining"

data availability

Data availability is a term used by some computer **storage** manufacturers and storage service providers (SSPs) to describe products and services that ensure that data continues to be available at a required level of performance in situations ranging from normal through "disastrous." In general, data availability is achieved through **redundancy** involving where the data is stored and how it can be reached. Some vendors describe the need to have a **data center** and a *storage-centric* rather than a *server-centric* philosophy and environment.

In large **enterprise** computer systems, computers typically access data over high-speed **optical fiber** connection to storage devices. Among the best-known systems for access are **ESCON** and **Fibre Channel**. Storage devices often are controlled as a redundant array of independent disks (**RAID**). Flexibility for adding and reconfiguring a storage system as well as automatically switching to a backup or failover environment is provided by a programmable or manually-controlled switch generally known as a *director*.

Two increasingly popular approaches to providing data availability are the storage area network (**SAN**) and network-attached storage (**NAS**). Data availability can be measured in terms of how often the data is available (one vendor promises 99.999% availability) and how much data can flow at a time (the same vendor promises 3200 megabytes per second).

data center

1) A data center is a centralized repository for the storage, management, and dissemination of data and information organized around a particular area or body of knowledge. For example, the National Climatic Data Center (NCDC) maintains the world's largest archive of weather information. Web site visitors can link to information about weather-related research or the forecast for a specific area. The NCDC responds to requests for weather data from all over the world.

2) A data center (sometimes spelled *datacenter*)—see also **hosting** and **application service provider**—is a specialized facility that houses Web sites and provides data serving and other services for other companies.

This kind of data center may contain a network operations center (NOC), which is a restricted access area containing automated systems that constantly monitor server activity,

#

Web traffic, and network performance and report even very slight irregularities to engineers so that they can spot potential problems before they happen.

A

3) In a company, data center is a term sometimes used to describe the central data processing facility and/or the group of people who manage the companies' data processing and networks.

B

C

Data Communication Equipment

See "DCE"

D

data dictionary

A data dictionary is a collection of descriptions of the **data** objects or items in a **data model** for the benefit of programmers and others who need to refer to them. A first step in analyzing a system of **objects** with which users interact is to identify each object and its relationship to other objects. This process is called data modeling and results in a picture of object relationships. After each data object or item is given a descriptive name, its relationship is described (or it becomes part of some structure that implicitly describes relationship), the type of data (such as text or image or binary value) is described, possible predefined values are listed, and a brief textual description is provided. This collection can be organized for reference into a book called a data dictionary.

E

F

G

H

I

J

K

L

M

N

O

P

When developing programs that use the data model, a data dictionary can be consulted to understand where a data item fits in the structure, what values it may contain, and basically what the data item means in real-world terms. For example, a bank or group of banks could model the data objects involved in consumer banking. They could then provide a data dictionary for a bank's programmers. The data dictionary would describe each of the data items in its data model for consumer banking (for example, "Account holder" and "Available credit").

Data Encryption Standard

Data Encryption Standard (DES) is a widely-used method of data **encryption** using a private (secret) key that was judged so difficult to break by the U.S. government that it was restricted for exportation to other countries. There are 72,000,000,000,000,000 (72 quadrillion) or more possible encryption keys that can be used. For each given message, the **key** is chosen at random from among this enormous number of keys. Like other private key cryptographic methods, both the sender and the receiver must know and use the same **private key**.

Q

R

S

T

U

V,W

X,Y,Z

DES applies a 56-bit key to each 64-bit block of data. The process can run in several modes and involves 16 rounds or operations. Although this is considered "strong" encryption, many companies use "triple DES", which applies three keys in succession. This is not to say that a DES-encrypted message cannot be "broken." Early in 1997,

Rivest-Shamir-Adleman, owners of another encryption approach, offered a \$10,000 reward for breaking a DES message. A cooperative effort on the Internet of over 14,000 computer users trying out various keys finally deciphered the message, discovering the key after running through only 18 quadrillion of the 72 quadrillion possible keys! Few messages sent today with DES encryption are likely to be subject to this kind of code-breaking effort.

DES originated at IBM in 1977 and was adopted by the U.S. Department of Defense. It is specified in the ANSI X3.92 and X3.106 standards and in the Federal FIPS 46 and 81 standards. Concerned that the encryption algorithm could be used by unfriendly governments, the U.S. government has prevented export of the encryption software. However, free versions of the software are widely available on bulletin board services and Web sites. Since there is some concern that the encryption algorithm will remain relatively unbreakable, NIST has indicated DES will not be recertified as a standard and a replacement has been selected. The new standard, known as the Advanced Encryption Standard (AES), uses the **Rijndael** algorithm.

data hiding

Data hiding is a characteristic of **object-oriented programming**. Because an **object** can only be associated with data in predefined classes or templates, the object can only "know" about the data it needs to know about. There is no possibility that someone maintaining the code may inadvertently point to or otherwise access the wrong data unintentionally. Thus, all data not required by an object can be said to be "hidden."

data integrity

See "integrity"

data key

In **cryptography**, a data key is a **key** (a variable value that is applied to a string or block of text to encrypt or decrypt it) that is used to encrypt or decrypt **data** only and is not used to encrypt or decrypt other keys, as some encryption formulas call for.

Another type of data key is an actual physical object, capable of storing digital information, that is used to store information and required to gain access to the data. An associated program and a mechanism called a *key analyser* enable the data to be processed by a computer. Some crypto systems require the combined use of a number of data keys belonging to separate individuals, so that **data integrity** is not reliant upon the trustworthiness of a single person.

data link control

DLC also is an abbreviation for **digital loop carrier**.

DLC (data link control) is the service provided by the **Data Link layer** of function defined in the Open Systems Interconnection (OSI) model for network communication. The Data Link layer is responsible for providing reliable data transfer across one physical link (or telecommunications path) within the network. Some of its primary functions include defining **frames**, performing error detection or **ECC** on those frames, and performing **flow control** (to prevent a fast sender from overwhelming a slow receiver).

Many point-to-point protocols exist at the Data Link layer including High-level Data Link Control (**HDLC**), Synchronous Data Link Control (**SDLC**), Link Access Procedure Balanced (LAPB), and Advanced Data Communications Control Procedure (ADCCP). All of these protocols are very similar in nature and are found in older networks (such as **X.25** networks). In the Internet, one of two point-to-point protocols are used at this layer: Serial Line Internet Protocol (**SLIP**) or Point-to-Point Protocol (**PPP**) with PPP being the newer, approved standard. All of these protocols are used in point-to-point connections such as those on metropolitan area network (**MAN**) or wide area network (**WAN**) **backbones** or when we dial our Internet service provider (**ISP**) from home using a modem.

In local area networks (**LANs**) where connections are multipoint rather than point-to-point and require more line-sharing management, the Data Link layer is divided into two sublayers: the **Logical Link Control layer** and the **Media Access Control layer**. The Logical Link Control layer protocol performs many of the same functions as the point-to-point data link control protocols described above. The Media Access Control (MAC) layer protocols support methods of sharing the line among a number of computers. Among the most widely used MAC protocols are **Ethernet** (IEEE 802.3), **Token Bus** (IEEE 802.4), and **Token Ring** (IEEE 802.5) and their derivatives.

data mart

A data mart is a repository of data gathered from operational data and other sources that is designed to serve a particular community of knowledge workers. In scope, the data may derive from an **enterprise-wide** database or **data warehouse** or be more specialized. The emphasis of a data mart is on meeting the specific demands of a particular group of knowledge users in terms of analysis, content, presentation, and ease-of-use. Users of a data mart can expect to have data presented in terms that are familiar.

In practice, the terms *data mart* and *data warehouse* each tend to imply the presence of the other in some form. However, most writers using the term seem to agree that the design of a data mart tends to start from an analysis of user needs and that a data warehouse tends to start from an analysis of what data already exists and how it can be collected in such a way

that the data can later be used. A data warehouse is a central aggregation of data (which can be distributed physically); a data mart is a data repository that may derive from a data warehouse or not and that emphasizes ease of access and usability for a particular designed purpose. In general, a data warehouse tends to be a strategic but somewhat unfinished concept; a data mart tends to be tactical and aimed at meeting an immediate need.

One writer, Marc Demerest, suggests combining the ideas into a Universal Data Architecture (UDA). In practice, many products and companies offering data warehouse services also tend to offer data mart capabilities or services.

data mining

Data mining is the analysis of data for relationships that have not previously been discovered. For example, the sales records for a particular brand of tennis racket might, if sufficiently analyzed and related to other market data, reveal a seasonal correlation with the purchase by the same parties of golf equipment.

Data mining results include:

- Associations, or when one event can be correlated to another event (beer purchasers buy peanuts a certain percentage of the time)
- Sequences, or one event leading to another later event (a rug purchase followed by a purchase of curtains)
- Classification, or the recognition of patterns and a resulting new organization of data (for example, profiles of customers who make purchases)
- Clustering, or finding and visualizing groups of facts not previously known
- Forecasting, or simply discovering patterns in the data that can lead to predictions about the future

The **data warehouse** concept is gaining acceptance in part because of the possibility of fruitful data mining.

data modeling

Also see: Unified Modeling Language (UML).

Data modeling is the analysis of data objects that are used in a business or other context and the identification of the relationships among these data objects. Data modeling is a first step in doing **object-oriented programming**. As a result of data modeling, you can then define the **classes** that provide the templates for program **objects**.

A simple approach to creating a data model that allows you to visualize the model is to draw a square (or any other symbol) to represent each individual data item that you know about (for example, a product or a product price) and then to express relationships between each of these data items with words such as “is part of” or “is used by” or “uses” and so forth. From such a total description, you can create a set of **classes** and subclasses that define all the

#

general relationships. These then become the templates for objects that, when executed as a program, handle the variables of new transactions and other activities in a way that effectively represents the real world.

Several differing approaches or methodologies to data modeling and its notation have recently been combined into the Unified Modeling Language (UML), which is expected to become a standard modeling language.

Data Over Cable Systems Interface

See "DOCSIS"

data set

In an IBM mainframe **operating system**, a data set is a named collection of data that contains individual data units organized (formatted) in a specific, IBM-prescribed way and accessed by a specific **access method** that is based on the data set organization. Types of data set organization include sequential, relative sequential, indexed sequential, and partitioned. Access methods include the Virtual Sequential Access Method (VSAM) and the Indexed Sequential Access Method (ISAM).

A data set corresponds to the concept of a **file** in other operating systems such as Linux and Windows 2000. *Data set organization* and *file format* are terms that have a close correspondence. A data set generally contains a collection of business data (names, salaries, sale figures, and so forth) whereas a file can contain many types of data (graphic images, audio data, video data, and so forth). For business data, the **database** is a newer alternative to the data set and the file.

A data set is also an older and now **deprecated** term for **modem**.

Data Space Transfer Protocol

See "DSTP"

Data Terminal Equipment

See "DTE"

data transfer rate

A data transfer rate (or often just *data rate*) is the amount of **digital data** that is moved from one place to another in a given time, usually in a second's time. The data transfer rate can be viewed as **the speed** of travel of a given amount of data from one place to another. In general, the greater the **bandwidth** of a given path, the higher the data transfer rate.

In telecommunications, data transfer is usually measured in bits per second. For example, a typical low-speed connection to the Internet may be 33.6 **kilobits** per second (Kbps). On **Ethernet** local area networks, data transfer can be as fast as 10 **megabits** per second. Network **switches** are planned that

will transfer data in the **terabit** range. In earlier telecommunication systems, data transfer was sometimes measured in characters or blocks (of a certain size) per second.

In computers, data transfer is often measured in **bytes** per second.

data type

A data type in a programming language is a set of **data** with values having predefined characteristics. Examples of data types are: integer, **floating point unit** number, **character**, string, and pointer. Usually, a limited number of such data types come built into a language. The language usually specifies the range of values for a given data type, how the values are processed by the computer, and how they are stored.

With **object-oriented programming**, a programmer can create new data types to meet application needs. Such an exercise as known as "data abstraction" and the result is a new **class** of data. Such a class can draw upon the "built-in" data types such as number integers and characters. For example, a class could be created that would abstract the characteristics of a purchase order. The purchase order data type would contain the more basic data types of numbers and characters and could also include other **objects** defined by another class. The purchase order data type would have all of the inherent services that a programming language provided to its built-in data types.

Languages that leave little room for programmers to define their own data types are said to be **strongly-typed** languages.

data warehouse

A data warehouse is a central repository for all or significant parts of the data that an enterprise's various business systems collect. The term was coined by W. H. Inmon. IBM sometimes uses the term "information warehouse." Typically, a data warehouse is housed on an enterprise **mainframe** server. Data from various online transaction processing (OLTP) applications and other sources is selectively extracted and organized on the data warehouse **database** for use by analytical applications and user queries. Data warehousing emphasizes the capture of data from diverse sources for useful analysis and access, but does not generally start from the point-of-view of the end user or knowledge worker who may need access to specialized, sometimes local databases. The latter idea is known as the **data mart**.

Data mining and a **decision support system** (DSS) are two of the kinds of applications that can make use of a data warehouse.

database

A database is a collection of **data** that is organized so that its contents can easily be accessed, managed, and updated. The most prevalent type of database is the **relational database**, a tabular database in which data is defined so that it can be reorganized and accessed in a number of different ways. A distributed database is one that can be dispersed or replicated among different points in a network. An **object-oriented programming** database is one that is congruent with the data defined in object classes and subclasses.

Databases contain aggregations of data records or files, such as sales transactions, product catalogs and inventories, and customer profiles. Typically, a database manager provides users the capabilities of controlling read/write access, specifying report generation, and analyzing usage. Databases and database managers are prevalent in large **mainframe** systems, but are also present in smaller distributed **workstation** and mid-range systems such as the AS/400 and on personal computers. **Structured Query Language** is a standard language for making interactive queries from and updating a database such as IBM's DB2, Microsoft's Access, and database products from Oracle, Sybase, and Computer Associates.

database administrator

DBA is also an abbreviation for *doing business as*—a term sometimes used in business and legal writing.

A database administrator (DBA) directs or performs all activities related to maintaining a successful **database** environment. Responsibilities include designing, implementing, and maintaining the database system; establishing policies and procedures pertaining to the management, security, maintenance, and use of the **database management system**; and training employees in database management and use. A DBA is expected to stay abreast of emerging technologies and new design approaches. Typically, a DBA has either a degree in Computer Science and some on-the-job training with a particular database product or more extensive experience with a range of database products. A DBA is usually expected to have experience with one or more of the major database management products, such as **DB2**, **SAP**, or Oracle-based database management software.

database management system

A database management system (DBMS), sometimes just called a *database manager*, is a program that lets one or more computer users create and access **data** in a **database**. The DBMS manages user requests (and requests from other programs) so that users and other programs are free from having to understand where the data is physically located on storage media and, in a multi-user system, who else may also be accessing the data. In handling user requests, the DBMS ensures the *integrity* of the data (that is, making sure it continues to be accessible and is consistently organized as

intended) and *security* (making sure only those with access privileges can access the data). The most typical DBMS is a relational database management system (**RDBMS**). A standard user and program interface is the Structured Query Language (**SQL**). A newer kind of DBMS is the object-oriented database management system (**ODBMS**).

A DBMS can be thought of as a *file manager* that manages data in databases rather than **files** in **file systems**. In IBM's **mainframe operating systems**, the nonrelational data managers were (and are, because these **legacy application** systems are still used) known as *access methods*.

A DBMS is usually an inherent part of a database product. On PCs, Microsoft Access is a popular example of a single- or small-group user DBMS. Microsoft's **SQL Server** is an example of a DBMS that serves database requests from multiple (**client**) users. Other popular DBMSs (these are all RDBMSs, by the way) are IBM's **DB2**, **Oracle's** line of database management products, and **Sybase's** products.

IBM's Information Management System (IMS) was one of the first DBMSs. A DBMS may be used by or combined with **transaction** managers, such as IBM's Customer Information Control System (**CICS**).

datagram

A datagram is, to quote the Internet's Request for Comments 1594, "a self-contained, independent entity of data carrying sufficient information to be routed from the source to the destination computer without reliance on earlier exchanges between this source and destination computer and the transporting network."

The term has been generally replaced by the term **packet**. Datagrams or packets are the message units that the **Internet Protocol** deals with and that the Internet transports. A datagram or packet needs to be self-contained without reliance on earlier exchanges because there is no connection of fixed duration between the two communicating points as there is, for example, in most voice telephone conversations. (This kind of protocol is referred to as *connectionless*.)

Data-Link layer

The Data-Link layer is the **protocol layer** in a program that handles the moving of data in and out across a physical link in a network. The Data-Link layer is layer 2 in the Open Systems Interconnection (**OSI**) model for a set of telecommunication protocols.

The Data-Link layer contains two sublayers that are described in the IEEE-802 LAN standards:

- Media Access Control (MAC)
- Logical Link Control (LLC)

The Data-Link layer ensures that an initial connection has been set up, divides output data into data frames, and handles the acknowledgements from a receiver that the data arrived successfully. It also ensures that incoming data has been received successfully by analyzing bit patterns at special places in the frames.

daughterboard

A daughterboard (or *daughter board*, *daughter card*, or *daughtercard*) is a circuit board that plugs into and extends the circuitry of another circuit board. The other circuit board may be the computer's main board (its **motherboard**) or it may be another board or card that is already in the computer, often a sound card. The term is commonly used by manufacturers of **wavetable** daughterboards that attach to existing sound cards.

A **mezzanine** card is a kind of daughterboard that is installed in the same plane as but on a second level above the motherboard.

DAW

See "digital audio workstation"

dB

See "decibel"

DB2

IBM's DB2 is a relational database management system (RDBMS) for large business computers that, according to IBM, leads in terms of database market share and performance. Although DB2 products are offered for UNIX-based systems and personal computer operating systems, DB2 trails **Oracle's** database products in UNIX-based systems and Microsoft's Access in Windows systems.

In addition to its offerings for the **mainframe OS/390** and **VM** operating systems and its mid-range **AS/400** systems, IBM offers DB2 products for a cross-**platform** spectrum that includes UNIX-based **Linux**, **HP-UX**, Sun **Solaris**, and SCO UnixWare; and for its personal computer **OS/2** operating system as well as for Microsoft's **Windows 2000** and earlier systems. DB2 databases can be accessed from any application program by using Microsoft's Open Database Connectivity (ODBC) interface, the Java Database Connectivity (JDBC) interface, or a **CORBA** interface broker.

DBA

See "database administrator"

DBMS

See "database management system"

DC

See also **Ohm's Law**.

DC (direct current) is the unidirectional flow or movement of electric charge carriers, usually **electrons**. The intensity of the **current** can vary with time, but the general direction of movement stays the same at all times. As an adjective, the term DC is used in reference to **voltage** whose polarity never reverses.

In a DC circuit, electrons emerge from the negative, or minus, pole and move towards the positive, or plus, pole. Nevertheless, physicists define DC as traveling from plus to minus.

Direct current is produced by electrochemical and photovoltaic cells and batteries. In contrast, the electricity available from utility mains in most countries is **AC** (alternating current). Utility AC can be converted to DC by means of a power supply consisting of a transformer, a rectifier (which prevents the flow of current from reversing), and a filter (which eliminates current pulsations in the output of the rectifier).

Virtually all electronic and computer hardware needs DC to function. Most solid-state equipment requires between 1.5 and 13.5 volts. Current demands can range from practically zero for an electronic wristwatch to more than 100 amperes for a radio communications power amplifier. Equipment using vacuum tubes, such as a high-power radio or television broadcast transmitter or a **CRT** (cathode-ray tube) display, require from about 150 volts to several thousand volts DC.

DCE

1) In network computing, DCE (Distributed Computing Environment) is an industry-standard software technology for setting up and managing computing and data exchange in a system of distributed computers. DCE is typically used in a larger network of computing systems that include different size servers scattered geographically. DCE uses the **client/server** model. Using DCE, application users can use applications and data at remote servers. Application programmers need not be aware of where their programs will run or where the data will be located.

Much of DCE setup requires the preparation of distributed directories so that DCE applications and related data can be located when they are being used. DCE includes security support and some implementations provide support for access to popular databases such as IBM's CICS, IMS, and DB2 databases.

DCE was developed by the Open Software Foundation (OSF) using software technologies contributed by some of its member companies.

2) In computer data transmission, DCE (Data Communication Equipment) is the **RS-232C** interface that a **modem** or other **serial** device uses in exchanging data with the

computer. For further information about the DCE interface and its relationship to the Data Terminal Equipment (DTE) interface, see **RS-232C**.

D-channel

In the Integrated Services Digital Network (**ISDN**), the D-channel is the channel that carries control and signalling information. (The “D” stands for “delta” channel.) The **B-channel** (“B” for “bearer”) carries the main data.

In ISDN, there are two levels of service: the Basic Rate Interface, intended for the home and small enterprise, and the Primary Rate Interface, for larger users. Both rates include a number of B- (bearer) channels and a D- (delta) channel. The B-channels carry data, voice, and other services. The D-channel carries control and signaling information.

The Basic Rate Interface consists of two 64 Kbps B-channels and one 16 Kbps D-channel. Thus, a Basic Rate Interface user can have up to 128 Kbps service. The Primary Rate Interface consists of 23 B-channels and one 64 Kbps D channel in the United States or 30 B-channels and 1 D-channel in Europe.

DCIT

DCIT (Digital Compression of Increased Transmission) is an approach to compressing information that compresses the entire transmission rather than just all or some part of the content. It can be applied on both wire and wireless media. It uses novel coding and modulation techniques devised at the Stevens Institute of Technology in Hoboken, New Jersey.

According to *IEEE Spectrum*, if equipment at home and the phone company’s central office used DCIT, existing copper wiring could deliver 3.2 Mbps in one direction and 8 to 16 Mbps in the other with a small amount of **bandwidth** available for **analog** voice transmission.

DCOM

DCOM (Distributed Component Object Model) is a set of Microsoft concepts and program interfaces in which **client** program **objects** can request services from **server** program objects on other computers in a network. DCOM is based on the **Component Object Model** (COM), which provides a set of interfaces allowing clients and servers to communicate within the same computer (that is running Windows 95 or a later version).

For example, you can create a page for a Web site that contains a script or program that can be processed (before being sent to a requesting user) not on the Web site server but on another, more specialized server in the network. Using DCOM interfaces, the Web server site program (now acting as a **client object**) can forward a Remote Procedure Call (**RPC**) to the specialized server object, which provides the necessary processing and returns the result to the Web server site. It passes the result on to the Web page viewer.

DCOM can also work on a network within an enterprise or on other networks besides the public Internet. It uses **TCP/IP** and **Hypertext Transfer Protocol**. DCOM comes as part of the Windows operating systems. DCOM is or soon will be available on all major UNIX platforms and on IBM’s large server products. DCOM replaces OLE Remote Automation.

DCOM is generally equivalent to the Common Object Request Broker Architecture (**CORBA**) in terms of providing a set of distributed services. DCOM is Microsoft’s approach to a network-wide environment for program and data objects. CORBA is sponsored by the rest of the information technology industry under the auspices of the Object Management Group (**OMG**).

DDCD

See “Double-Density Compact Disk”

DDE

See “Dynamic Data Exchange”

DDK

See “driver development kit”

DDoS attack

See “distributed denial-of-service attack”

DDR SDRAM

DDR SDRAM (double data rate SDRAM) is synchronous dynamic RAM (**SDRAM**) that can theoretically improve **memory** clock speed to at least 200 MHz*. It activates output on both the rising and falling edge of the system clock rather than on just the rising edge, potentially doubling output. It’s expected that a number of **Socket 7** **chipset** makers will support this form of **SDRAM**.

*Synchronous DRAM speed is measured in MHz rather than **nanoseconds**. You can convert the RAM clock speed to nanoseconds by dividing the chip speed into 1 billion ns (which is one second). For example, an 83 MHz RAM would be equivalent to 12 ns.

See “Digital Data Storage”

dead media

In 1995, science-fiction writer Bruce Sterling challenged a conference of computer artists and the world at large to help identify the extinct species in the new media taxonomy and face the fact that, for each new medium or technology that

survives, dozens fall by the wayside. Sterling insisted that it's important to recognize, pay homage to, and ponder the "dead media" that seem, once fallen, to pass so quickly from the scene. As a result of Sterling's challenge, fellow enthusiasts have begun to chronicle artifacts of information technology going back to earliest times. Among the inventions cataloged as part of the Dead Media Project are:

- "Primitive" (but not considered so at the time) stone-carvings, bead and knitted mnemonic and historical recordings, stone formations, drum signals, shouting networks, alpenhorns, whistling networks, and town criers
- Early postal systems such as Thurn and Taxis and the U.S. Pony Express
- Many systems of optical telegraphy
- Giovanni Caselli's fascimile pantelegraph
- The chronophotographoscope, Cinerama, and Cinemascope
- Early digital networks, such as Teletext, Viewtron, Viewdata, Prestel, The Source, Qube, Alex (Quebec), Telidon (Canada), Viatel and Discovery 40 (Australia).

deadlock

A deadlock is a situation in which two computer programs sharing the same resource are effectively preventing each other from accessing the resource, resulting in both programs ceasing to function.

The earliest computer **operating systems** ran only one program at a time. All of the resources of the system were available to this one program. Later, operating systems ran multiple programs at once, interleaving them. Programs were required to specify in advance what resources they needed so that they could avoid conflicts with other programs running at the same time. Eventually some operating systems offered dynamic allocation of resources. Programs could request further allocations of resources after they had begun running. This led to the problem of the deadlock. Here is the simplest example:

Program 1 requests resource A and receives it.

Program 2 requests resource B and receives it.

Program 1 requests resource B and is queued up, pending the release of B.

Program 2 requests resource A and is queued up, pending the release of A.

Now neither program can proceed until the other program releases a resource. The operating system cannot know what action to take. At this point the only alternative is to abort (stop) one of the programs.

Learning to deal with deadlocks had a major impact on the development of operating systems and the structure of databases. Data was structured and the order of requests was constrained in order to avoid creating deadlocks.

Debian Linux

See "Debian"

Debian

Debian is a popular and freely-available computer **operating system** that uses the **Linux kernel** and other program components obtained from the **GNU** project. Debian can be downloaded over the Internet or, for a small charge, obtained on CD. As **Open Source** software, Debian is developed by over 500 contributing programmers who collectively form the Debian Project. New releases are provided from time to time. Ongoing service is available through subscription to a mailing list.

Debian supports over 3,950 free, downloadable applications. Although some widely-used applications such as Microsoft Word and Excel are not included, Corel's WordPerfect and similar desktop applications are available.

Debian was one of the first free software projects, begun in 1993 by Ian Murdock. Debian is pronounced deb-EE-uhh since it derives from the names of Ian Murdock and his wife, Debra.

debouncing

Bouncing is the tendency of any two metal contacts in an electronic device to generate multiple signals as the contacts close or open; debouncing is any kind of hardware device or software that ensures that only a single signal will be acted upon for a single opening or closing of a contact.

When you press a key on your computer **keyboard**, you expect a single contact to be recorded by your computer. In fact, however, there is an initial contact, a slight bounce or lightening up of the contact, then another contact as the bounce ends, yet another bounce back, and so forth. A similar effect takes place when a switch made using a metal contact is opened. The usual solution is a debouncing device or software that ensures that only one digital signal can be registered within the space of a given time (usually milliseconds).

debugging

In computers, debugging is the process of locating and fixing or bypassing **bugs** (errors) in computer program code or the engineering of a hardware device. To debug a program or hardware device is to start with a problem, isolate the source of the problem, and then fix it. A user of a program that does not know how to fix the problem may learn enough about the problem to be able to avoid it until it is permanently fixed. When someone says they've debugged a program or "worked the bugs out" of a program, they imply that they fixed it so that the bugs no longer exist.

Debugging is a necessary process in almost any new software or hardware development process, whether a commercial product or an enterprise or personal application program. For complex products, debugging is done as the result of the unit test for the smallest unit of a system, again at component test when parts are brought together, again at system test when the product is used with other existing products, and again during customer **beta test**, when users try the product out in a real world situation. Because most computer programs and many programmed hardware devices contain thousands of lines of code, almost any new product is likely to contain a few bugs. Invariably, the bugs in the functions that get most use are found and fixed first. An early version of a program that has lots of bugs is referred to as “buggy.”

Debugging tools help identify coding errors at various development stages. Some programming language packages include a facility for checking the code for errors as it is being written.

DEC

Now part of Compaq, DEC (Digital Equipment Corporation) has long occupied a leading position in the mid-range computer, traditionally known as the **minicomputer**, the business computer platform that fits between the mainframe and the personal computer and serves small and medium-sized businesses with its **VMS** operating system. In recent years, DEC has been addressing IBM’s **AS/400** platform, the advent of the **workstation** platforms of Sun Microsystems and others, and the **client/server** concept of computing. Today, DEC is focusing strongly on Internet systems and software.

decibel

In electronics and communications, the decibel (abbreviated as dB, and also as db and DB) is a **logarithmic** expression of the ratio between two signal power, **voltage**, or **current** levels. In acoustics, the decibel is used as an absolute indicator of sound power per unit area. A decibel is one-tenth of a Bel, a seldom-used unit named for Alexander Graham Bell, inventor of the telephone.

Suppose a signal has a power of P_1 watts, and a second signal has a power of P_2 watts. Then the power amplitude difference in decibels, symbolized S_{dBp} , is:

$$S_{dBp} = 10 \log_{10} (P_2/P_1)$$

Decibels can be calculated in terms of the effective voltage if the load **impedance** remains constant. Suppose a signal has an rms (**root-mean-square**) voltage of V_1 across a load, and a second signal has an rms voltage of V_2 across another load having the same impedance. Then the voltage amplitude difference in decibels, symbolized S_{dBv} , is:

$$S_{dBv} = 20 \log_{10} (V_2/V_1)$$

Decibels can also be calculated in terms of the effective current (amperage) if the impedance remains constant. Suppose a signal delivers an rms (root-mean-square) amperage of A_1 through a load, and a second signal delivers an rms amperage of A_2 through another load having the same impedance. Then the current amplitude difference in decibels, symbolized S_{dBA} , is:

$$S_{dBA} = 20 \log_{10} (A_2/A_1)$$

When a decibel figure is positive, then the second signal is stronger than the first signal. When a decibel figure is negative, then the second signal is weaker than the first signal. In amplifiers, the gain, also called the amplification factor, is often expressed in decibels. A circuit amplifies only if the decibel figure for the output-to-input power ratio (S_{dBp}) is positive.

In sound, decibels are defined in terms of power per unit surface area on a scale from the threshold of human hearing, 0 dB, upward towards the threshold of pain, about 120–140 dB. As examples: the sound level in the average residential home is about 40 dB, average conversation is about 60 dB, typical home music listening levels are about 85 dB, a loud rock band about 110 dB, and a jet engine close up is 150dB.

Decibel units are commonly used in audio equalizers, both the hardware kind and the software kind, as a convenient reference point while editing. Boosting an equalizer band whose center point is 1000 by 3 dB means that you have raised the volume level of that frequency band by 3 dB as it relates to the other frequencies in the sound. A typical equalizer has a range for boosting or diminishing a sound level of $+/-18$ dB.

decipher

All three terms—decipher, decrypt, and decode—mean to convert **ciphertext** into the original, unencrypted **plaintext**. *Decrypt* is actually a generic term, covering both the other terms, that simply means to unscramble a message. The root prefix *crypto* is from the Greek *kryptos*, meaning *hidden or secret*.

Although *decipher* and *decode* are frequently used interchangeably, in the strictest sense, a distinction can be made between the two. Both terms refer to a system of encryption in which message data is replaced with other data to make it unreadable. The crucial difference between *decipher* and *decode* lies in the level of substitution used: In some security contexts, a message encrypted through the use of a **cipher** works with substitution at the level of letters; to *decipher* means to unscramble a message that uses substitution at the letter level. According to some accounts, Julius Caesar developed a cipher to encrypt messages so that they could be sent without fear that the messenger would betray him. Caesar replaced each letter in his message with the one three positions ahead of it in the alphabet, so that, for example, “A” became “D,” “C” became “F” and so on. Only someone in possession of Caesar’s encryption rule (or **key**)

could read the message, by performing the opposite operation: substitute each letter with the one three positions *before* it in the alphabet. Caesar's encrypted message is an example of **ciphertext** and the unencrypted message an example of **plaintext**; the mathematical formula (shift by 3) used for encryption and decryption is a simple example of an **algorithm**.

In contexts where a distinction is made between decipher and decode, to *decode* means to unscramble a message in which text is transformed through the substitution of words or phrases, since, in this context, encoded messages are encrypted at the level of words or phrases.

decision support system

A decision support system (DSS) is a computer program application that analyzes business data and presents it so that users can make business decisions more easily. It is an "informational application" (in distinction to an "operational application" that collects the data in the course of normal business operation). Typical information that a decision support application might gather and present would be:

- Comparative sales figures between one week and the next
- Projected revenue figures based on new product sales assumptions
- The consequences of different decision alternatives, given past experience in a context that is described

A decision support system may present information graphically and may include an expert system or artificial intelligence (AI). It may be aimed at business executives or some other group of knowledge workers.

decryption

See "encryption"

DECT

Unlike the **analog** cordless phones you may have in your home, DECT (Digital Enhanced Cordless Telecommunications) is a **digital wireless** telephone technology that is expected to make cordless phones much more common in both businesses and homes in the future. Formerly called the

Digital European Cordless Telecommunications standard because it was developed by European companies, DECT's new name reflects its global acceptance. Like another important wireless standard, **Global System for Mobile communication**, DECT uses time division multiple access (TDMA) to transmit radio signals to phones. Whereas GSM is optimized for mobile travel over large areas, DECT is designed especially for a smaller area with a large number of users, such as in cities and corporate complexes. A user can have a telephone equipped for both GSM and DECT (this is known as a *dual-mode* phone) and they can operate seamlessly.

DECT has five major applications:

- 1) The "**cordless private branch exchange**." A company can connect to a wired telephone company and redistribute signals by radio antenna to a large number of telephone users within the company, each with their own number. A cordless PBX would be especially useful and save costs in a company with a number of mobile employees such as those in a large warehouse.
- 2) **Wireless Local Loop (WLL)**. Users in a neighborhood typically served by a telephone company wired **local loop** can be connected instead by a cordless phone that exchanges signals with a neighborhood antenna. A standard telephone (or any device containing a telephone such as a computer **modem** or **fax machine**) is simply plugged into a fixed access unit (FAU), which contains a transceiver. The Wireless Local Loop would typically be installed in an urban area where many users could share the same antenna.
- 3) **Cordless Terminal Mobility**. The arrangement used by businesses for a cordless PBX could also be used by a service that provided cordless phone numbers for individual subscribers. In general, the mobility would be less than that available for GSM users.
- 4) **Home cordless phones**. A homeowner could install a single-**cell** antenna within the home and use it for a number of cordless phones throughout the home and garden.
- 5) **GSM/DECT internetworking**. Part of the DECT standard describes how it can interact with the GSM standard so that users can be free to move with a telephone from the outdoors (and GSM signals) into an indoor environment (and a DECT system). It's expected that many GSM service providers may want to extend their service to support DECT signals inside buildings. A dual-mode phone would automatically search first for a DECT connection, then for a GSM connection if DECT is not available.

dedicated hosting

See "dedicated server"

dedicated line

A dedicated line is a telecommunications path between two points that is available 24 hours a day for use by a designated user (individual or company). It is not shared in common among multiple users as **dial-up** lines are. A dedicated line can be a physical path owned by the user or rented from a telephone company, in which case it is called a **leased line**. A synonym is *nonswitched line* (as opposed to a *switched* or dial-up line).

dedicated server

In the Web **hosting** business, a dedicated server refers to the rental and exclusive use of a computer that includes a **Web server**, related software, and connection to the Internet, housed in the Web hosting company's premises. A dedicated server is usually needed for a **Web site** (or set of related company sites) that may develop a considerable amount of traffic—for example, a site that must handle up to 35 million **hits** a day. The server can usually be configured and operated remotely from the client company. Web hosting companies claim that the use of a dedicated server on their premises saves router, Internet connection, security system, and network administration costs.

In renting a dedicated server, the client company may be required to use a specified computer system or may be offered a choice of several systems. Some host providers allow a client company to purchase and install its own computer server at the host provider's location, a service known as **colocation**.

Typically, a dedicated server is rented that provides a stated amount of **memory**, hard disk space, and bandwidth (here meaning the number of **gigabytes** of data that can be delivered each month). Some hosting companies allow the renter of a dedicated server to do **virtual hosting**, in turn renting services on the server to third parties for their Web sites. **Domain name system**, e-mail, and File Transfer Protocol (**FTP**) capabilities are typically included and some companies provide an easy-to-use control interface.

deep link

A deep link is a **hypertext link** to a **page** on a **Web site** other than its **home page**. The "deep" refers to the depth of the page in a site's hierarchical structure of pages. Any page below the top page in the hierarchy (the home page) can thus be considered deep. The term has been given prominence in the legal suit of the Ticketmaster Corporation against Microsoft. A Microsoft-owned site (one of its Sidewalk sites) linked to a page of useful information within the Ticketmaster site, avoiding the Ticketmaster home page. Ticketmaster sued Microsoft for linking without permission, claiming that they were thus being deprived of advertising viewers for the ads on their home page. In fact, their content was appearing within a Microsoft page containing their advertising.

In his TBTF Newsletter, Keith Dawson refers to deep links as "rifle shots," suggesting that they get the Web surfer immediately to the information they want. Although no one has quantified the number of deep links between Web sites, it would certainly seem to be a very large number. Most major search engine and directory sites like Yahoo invite Web sites to request inclusion with the assumption that all pages will be indexed unless explicitly excluded. And, undoubtedly, most sites welcome links from anywhere to any of their pages.

Although the issue is still to be fully resolved, some observers think it likely that the prevalence of deep links on the Web will continue as an essential characteristic. Brad Templeton, writing at one Web site, suggests that most Web sites implicitly encourage both home page and deep links simply by being part of the Web. He suggests that those sites that want to inhibit deep links to their site could state it clearly as a way to discourage such links. Many feel that the practice of "framing" another site within a **frame** on your site poses some liability for the framing site, unless permission to frame is received first.

Deep Space Network

The Deep Space Network (DSN) is a sophisticated data communications system used by NASA (the U.S. National Aeronautics and Space Administration) in conjunction with manned and unmanned space missions. The DSN is also used by radio astronomers.

The main terminal of the DSN is located at JPL (Jet Propulsion Laboratory) headquarters in Pasadena, California. There are three primary antennas, spaced equally on a great circle that slants around the world. All three are large paraboloid (dish) antennas that can be used for transmitting and receiving signals over a wide range of radio frequencies. One antenna is located in California, another is in Spain, and another is in Australia. The antennas are located in such a way that all existing operational spacecraft can be monitored and controlled, and communications maintained with them, almost 100 percent of the time. This is true of both earth-orbiting **satellites** and interplanetary space vehicles.

Signals transmitted and received by DSN equipment include satellite control and telemetry, e-mail (including text, graphics, video, programs, and sound attachments), communications with the Space Shuttles, and radio-frequency emanations from distant celestial objects.

deep Web

The deep Web is the hidden part of the Web, containing a huge volume of content that is inaccessible to conventional **search engines**, and consequently, to most users. According to a recent study by BrightPlanet, a search technology company, the deep web may contain 550 billion documents, perhaps 500 times the content of the surface Web that most

#

v,w

x,y,z

of us are familiar with. In comparison, Google—which claims to index the most comprehensive collection of documents on the Internet—has identified 1.2 billion documents and is actually capable of searching a mere 600 million of those. An article in *Nature* reported that even a large search engine such as Northern Light only indexes 16% of even the surface Web's content. These figures indicate that an Internet search typically searches .03% ($1/3000$) of available content.

In addition to the surprising quantity of deep Web content in existence, BrightPlanet found that the deep Web was growing much more quickly than the surface Web, and that the quality of the content within it—95% of which is publicly accessible—was significantly higher than the vast majority of surface Web content. According to *The Standard*, among the myriad offerings of the deep Web are: Securities and Exchange Commission filings, telephone yellow pages, IBM's patent database, the Merriam-Webster Dictionary, and Kelly Blue Book information on automobiles. In order to access these and other deep Web content, however, a user must know the exact **URL** of the target Web page. A number of companies are now offering search tools with the capacity to simultaneously search through multiple deep Web databases, including IntelliSeek's Bulls Eye software and BrightPlanet's own **LexiBot**.

default

In computer technology, a default (noun, pronounced dee-FAWLT) is a predesigned value or setting that is used by a computer program when a value or setting is not specified by the program user. The program user can be either an interactive user of a **graphical user interface** or command line interface, or a programmer using an **application program interface**. When the program receives a request from an interactive user or another program, it looks at the information that has been passed to it. If a particular item of information is not specified in the information that is passed, the program uses the default value that was defined for that item when the program was written. In designing a program, each default is usually preestablished as the value or setting that most users would probably choose. This keeps the interface simpler for the interface user and means that less information has to be passed and examined during each program request.

To the program requestor, to default (verb) is to intentionally or accidentally allow the preestablished value or setting for an item to be used by the program. The program is said to default when it uses a default value or setting.

Default (adjective) pertains to something that is used when something else is not supplied or specified. For example, a default printer is a type of printer that is assumed to be connected to a computer unless the computer user specifies another type that is actually connected.

Defense Advanced Research Projects Agency Network

See "DARPA^{Net}"

Defense Advanced Research Projects Agency

See "DARPA"

Defense Message System

The Defense Message System (DMS) is a secure **X.400**-based e-mail system developed by the United States government in conjunction with industry partners to ensure safety for critical operations. Essentially an enhanced version of various commercial e-mail products, DMS was developed for the United States Department of Defense (DoD). DMS has replaced AUTODIN (*automated digital network*), the previous official DoD e-mail system as well as 45 separate e-mail systems that functioned within the DoD.

At the **client** level, DMS looks like a typical e-mail application and is designed to feature familiar user-friendly functionality, such as global **X.500** Directory Service, and transmission support for digital files of any type and size. Security and delivery assurance mechanisms are approved by the National Security Agency (NSA) for information classified at all levels, up to and including those designated as top secret. Because sending message attachments between the unclassified and secret domains (known, respectively, as *NIPRNET* and *SIPRNET*) requires protection against leakage of classified information, DMS policies require that all organizational messages be signed and encrypted with Class IV Public Key Infrastructure (**PKI**) protection through **Fortezza**, NSA's trademarked security products suite. Originally policies permitted organizational message attachments to be sent only from a low security domain to a high security domain, but security mechanisms (both technological and policy-based) are now in place to allow the information to flow in either direction.

DMS was designed to incorporate components from a variety of leading hardware and software vendors and to leverage the best current and emerging messaging technologies within the Defense Information Infrastructure (DII, a worldwide connectivity transport infrastructure). The DMS development program began in response to Joint Staff requirements for an integrated messaging service that could be accessed from any DoD location in the world, as well as by designated government users or contractors. DMS has been recommended to become the standard messaging system throughout the U.S. government.

defragmenter

When a file is too large to store in a single location on a **hard disk**, it is stored on the disk in discontinuous (not adjacent) parts or fragments. This fragmentation is "invisible" to the

user; however. The locations of the fragments are kept track of by the system. Over time, disk access time can be slowed by fragmentation since each fragmented file is likely to require multiple drive head repositionings and accesses. (There's nothing you can do to prevent fragmentation, by the way.)

A disk defragmenter is a utility that rearranges your fragmented files and the free space on your computer so that files are stored in contiguous units and free space is consolidated in one contiguous block. This also improves access time to files that are now contiguous.

A defragmenter utility comes with the DOS 6.0 and with Windows operating systems. In DOS, you can defragment a drive using the DEFRAG command. In Windows operating systems, you'll find "Defragmenter" by going from the Start Menu to Programs, to Accessories, to System Tools, and to Defragmenter. Separate products, sometimes called disk optimizers, will also defragment your disk.

degauss

To degauss (pronounced dee-GOWS) is to demagnetize. Degaussing a computer display removes any undesirable magnetic field that may have built up within the display, causing distortion of the image or color. Display **monitors** with cathode ray tube (CRT) technology are subject to the buildup of magnetic fields. Many display manufacturers include an internal coil that will degauss the display when it is turned on. Some displays also include an external control that a user can operate to degauss the display at any time.

Degaussing a magnetic storage medium removes all the data stored on it. A *degausser* is a device used for this purpose.

delimiter

In computer programming, a delimiter is a **character** that identifies the beginning or the end of a character string (a contiguous sequence of characters). The delimiting character is not part of the character string. In command syntax, a space or a backslash () or a forward slash (/) is often a delimiter, depending on the rules of the command language. The program interpreting the character string knows what the delimiters are.

Delimiters can also be used to separate the data items in a **database** (the columns in the database table) when transporting the database to another application. For example, a comma-separated values file (CSV file) is one in which each value in the cells of a table row is delimited by and separated from the next value by a comma. The beginning of a row is indicated by a new line character.

demarc

A demarc (an abbreviation for *demarcation point*) marks the point where communications facilities owned by one organization **interface** with that of another organization. In

telephone terminology, this is the interface between *customer-premises equipment* and network service provider equipment.

A synonym is *network terminating interface (NTI)*.

demilitarized zone

See "DMZ"

demo

See "demo and demoscene"

demo and demoscene

In Internet terminology, a demo (sometimes called a *PC demo*, although generally the PC is considered to be implicit) is a non-interactive **multimedia** presentation, the computer world's equivalent of a music video. Demos are usually made to showcase some or all of the following: computer hardware and/or software capabilities (such as multi-channel sound or 3-D effects); the subject of the demo (such as a product or a musician); and the abilities of the programmer (such as complex motion). Demos are frequently played in competitions, which classify them as belonging to one of three subsets: the *intro 4k*, which is fairly basic and generally has no music; the *intro 64k*, no restrictions other than size; and the full-fledged *demo*, which may contain any possible media. Demos are the work of computer enthusiasts who often spend many days (or even weeks or months) creating a demo that may not have any external motivation (such as money, or acclaim in the broader world).

The typical demo creator (known as a *demomaker*) is a male between the ages of 15 and 30, typically a student who is identified by a pseudonym. Demomakers are part of a subculture called the demoscene, an underground community that is reported to number among its members the elite from the worlds of programming and computer-assisted composing and art. Because each demo may showcase several talents, demomakers with complementary skills often collaborate to form *demogroups* that, like demomakers themselves, are identified by a special name and create their own mystique and reputation. Demomakers gather frequently for *demoparties*, which are arranged around competitions. Some of the largest demoparties have assembled over 4,300 demomakers. The demoscene originated in Europe and is most active in Scandinavia, Denmark, Germany, The Netherlands, Switzerland, Poland and France, although it is gradually making its presence felt in the rest of the world.

demographics

Demographics is the study of the behaviors and other characteristics of groups of human beings in terms of statistics.

B

C

demon

A demon (also see **daemon** which has a somewhat similar meaning) is a program or process, part of a larger program or process, that is dormant until a certain condition occurs and then is initiated to do its processing. Eric Raymond cites an artificial intelligence (**artificial intelligence**) application as an example. An AI program might include a number of demons, one or more of which might become active when a new piece of knowledge was acquired by the AI program. If the new knowledge affected a particular demon's own sphere of knowledge, it would spring into action and create new pieces of knowledge based on its particular inference rules. Each of these new pieces of knowledge might in turn activate additional demons that would continue to filter through and refine the entire AI knowledge base.

E

A second example of a demon may be found in personal computer help systems, games, or any application where, when a program so determines by the state of the user interactions with the program, a "popup" window and program is introduced to the user for help, a clue, or a small calculation.

DEN

Directory-Enabled Networking (DEN) is an industry-standard initiative and specification for how to construct and store information about a network's users, applications, and data in a central directory. A standard way of describing the network's elements in a central repository can enable applications to be developed that will automatically learn of user access privileges, bandwidth assignments, and the company's resource policies, and provide services accordingly. The result should reduce the cost of running the network and enable new services.

P

Q

R

S

T

U

DEN defines an **object-oriented** information model that is based on another recent standard initiative, the Common Information Model (CIM). Both models are being mapped into the directory defined as part of the Lightweight Directory Access Protocol (**LDAP**). DEN and CIM are an

v,w

x,y,z

advance over and can be used with the Simple Network Management Protocol (**Simple Network Management Protocol**).

With DEN, a client/server application on the network can be designed to automatically provide the user with the proper level of access to its resources without needing manual assistance from a network administrator when the user changes locations or positions within the company. In the past, the proper level of access has required significant manual assistance to implement and maintain. Information that may affect access can include not only the user's own access privileges but also network resource availability in terms of bandwidth and services.

By entering specific information about the network in the central directory using the DEN model and syntax, network information then becomes available to any DEN-enabled application in the network. When a user attempts to open one of these types of applications on the network, the application checks dynamically in the LDAP global directory in order to see what the user's access privileges should be. The application can then automatically open and configure itself to provide the correct level of access to its features, based on the usage policy information it has located in the LDAP directory.

An example of a "DEN-enabled application" is the Microsoft **Windows NT** operating system, Version 5.0 or higher, which includes the Active Directory Service, an implementation of DEN. DEN was developed by 70 companies, including Microsoft and Cisco. In late 1998, the Desktop Management Task Force (DMTF) took over the DEN work on network data models and began integrating it into its own Common Information Model (CIM).

dendrimer

A dendrimer (from Greek *dendra* for tree) is an artificially manufactured or synthesized molecule built up from branched units called monomers. Such processes involve working on the scale of nanometers (a nanometer is 10^{-9} meter or a millionth of a millimeter). Technically, a dendrimer is a polymer, which is a large molecule comprised of many smaller ones linked together.

Dendrimers have some proven applications, and numerous potential applications. They have been used in the production of industrial adhesives. They are expected to serve as components in a variety of nanomachines. Dendrimers are of interest to researchers in medical technology, where they might help carry and deliver drugs in the body, or serve as replacements for plasma components. Dendrimers might also prove useful in the manufacture of nanoscale batteries and lubricants, catalysts, and herbicides.

Also see **nanomachine** and **nanotechnology**.

deniable encryption

Deniable **encryption** is a type of **cryptography** that allows an encrypted text to be decrypted in two or more ways, depending on which decryption **key** is used. The use of two or more keys allows the sender, theoretically, to conceal or deny the existence of a controversial message in favor of a more benign decryption. For instance, a company may send an encrypted message to its high-level administrative staff whose key decrypts the message to read “We have no plans to change our business model,” while the board of directors receives the same message that using its own key decrypts the same message to read “We are going bankrupt at this rate and need to let 20,000 people go, including high-level administrators.” Deniable encryption is sometimes used for misinformation purposes when the sender anticipates, or even encourages, interception of a communication.

denial of service

On the Internet, a denial of service (DoS) attack is an incident in which a user or organization is deprived of the services of a resource they would normally expect to have. Typically, the loss of service is the inability of a particular network service, such as e-mail, to be available or the temporary loss of all network connectivity and services. In the worst cases, for example, a Web site accessed by millions of people can occasionally be forced to temporarily cease operation. A denial of service attack can also destroy programming and files in a computer system. Although usually intentional and malicious, a denial of service attack can sometimes happen accidentally. A denial of service attack is a type of security breach to a computer system that does not usually result in the theft of information or other security loss. However, these attacks can cost the target person or company a great deal of time and money.

Common forms of denial of service attacks are:

Buffer Overflow Attacks

The most common kind of DoS attack is simply to send more traffic to a network address than the programmers who planned its data **buffers** anticipated someone might send. The attacker may be aware that the target system has a weakness that can be exploited or the attacker may simply try the attack in case it might work. A few of the better-known attacks based on the buffer characteristics of a program or system include:

- Sending e-mail messages that have attachments with 256-character file names to Netscape and Microsoft mail programs
- Sending oversized Internet Control Message Protocol (ICMP) **packets** (this is also known as the Packet Internet or Inter-Network Groper (PING) of death)
- Sending to a user of the **Pine** e-mail program a message with a “From” address larger than 256 characters

SYN Attack

When a session is initiated between the Transport Control Program (TCP) client and server in a network, a very small buffer space exists to handle the usually rapid “hand-shaking” exchange of messages that sets up the session. The session-establishing **packets** include a SYN field that identifies the sequence in the message exchange. An attacker can send a number of connection requests very rapidly and then fail to respond to the reply. This leaves the first **packet** in the buffer so that other, legitimate connection requests can’t be accommodated. Although the packet in the buffer is dropped after a certain period of time without a reply, the effect of many of these bogus connection requests is to make it difficult for legitimate requests for a session to get established. In general, this problem depends on the operating system providing correct settings or allowing the network administrator to tune the size of the buffer and the timeout period.

Teardrop Attack

This type of denial of service attack exploits the way that the Internet Protocol (IP) requires a packet that is too large for the next router to handle be divided into fragments. The fragment packet identifies an offset to the beginning of the first packet that enables the entire packet to be reassembled by the receiving system. In the teardrop attack, the attacker’s IP puts a confusing offset value in the second or later fragment. If the receiving operating system does not have a plan for this situation, it can cause the system to crash.

Smurf Attack

In this attack, the perpetrator sends an IP ping (or “echo my message back to me”) request to a receiving site. The ping packet specifies that it be broadcast to a number of hosts within the receiving site’s local network. The packet also indicates that the request is from another site, the target site that is to receive the denial of service. (Sending a packet with someone else’s return address in it is called **spoofing** the return address.) The result will be lots of ping replies flooding back to the innocent, spoofed host. If the flood is great enough, the spoofed host will no longer be able to receive or distinguish real traffic.

Viruses

Computer **viruses**, which replicate across a network in various ways, can be viewed as denial-of-service attacks where the victim is not usually specifically targeted but simply a host unlucky enough to get the virus. Depending on the particular virus, the denial of service can be hardly noticeable ranging all the way through disastrous.

Physical Infrastructure Attacks

Here, someone may simply snip a fiber optic cable. This kind of attack is usually mitigated by the fact that traffic can sometimes quickly be rerouted.

There are ways of preventing many forms of DoS attacks.

denial-of-service attack

See "denial of service"

dense wavelength division multiplexing

Dense wavelength division multiplexing (DWDM) is a technology that puts data from different sources together on an **optical fiber**, with each signal carried on its own separate light **wavelength**. Using DWDM, up to 80 (and theoretically more) separate wavelengths or **channels** of data can be multiplexed into a lightstream transmitted on a single optical fiber. Each channel carries a time-division multiplexed (TDM) signal. In a system with each channel carrying 2.5 **Gbps** (billion bits per second), up to 200 billion bits can be delivered a second by the optical fiber. DWDM is also sometimes called *wave division multiplexing* (WDM).

Since each channel is demultiplexed at the end of the transmission back into the original source, different data formats being transmitted at different data rates can be transmitted together. Specifically, Internet (IP) data, Synchronous Optical Network data (SONET), and asynchronous transfer mode (ATM) data can all be travelling at the same time within the optical fiber.

DWDM promises to solve the "**fiber exhaust**" problem and is expected to be the central technology in the all-optical networks of the future.

deploy

To deploy (from the French *deployer*) is "to spread out or arrange strategically." Long used in the context of military strategy, it has now gained currency in information technology, especially in **distributed** computing.

deprecated

Deprecated means tolerated but not recommended. A number of elements and attributes are deprecated in **HTML 4.0**, meaning that other methods of accomplishing the task are preferred. Deprecated features may become obsolete in future versions of HTML, though browsers that support the features may continue to support them.

DES

See "Data Encryption Standard"

desktop computer

Also see **portable computer** and **notebook computer**.

A desktop computer is a personal computer that is designed to fit conveniently on top of a typical office desk. A desktop computer typically comes in several units that are connected together during installation: (1) the **processor**, which can be in a *microtower* or *minitower* designed to fit under the desk or in a unit that goes on top of the desk, (2) the **display monitor**, (3) and input devices—usually a **keyboard** and a **mouse**. Today, almost all desktop computers include a built-in **modem**, a **CD-ROM** drive, a multi-**gigabyte** magnetic storage drive, and sometimes a **diskette** drive. At home, most desktop computer users also purchase a **printer**. In businesses and increasingly at home, desktop computers can be interconnected and can share resources such as printers by being connected to a local area network (LAN).

Desktop Management Interface

See "DMI"

desktop theme

A desktop theme is a customized graphical user interface (GUI) that replaces a computer's ordinary sounds, icons, pointer, wallpaper or screensaver with something designed to reflect the interests of the user. For instance, if you were interested in bass fishing, you could have a picture of a lake for your computer wallpaper, icons that resemble different kinds of fishing lures, sounds that are related to boats, water and fishing reels, a screen saver from your favorite TV show about bass fishing, and a pointer that looks like a fish. Although desktop themes are popular for home use, many network administrators frown upon desktop themes, primarily because it is possible for a user to inadvertently introduce a virus by downloading a theme from an unknown source.

There are free desktop themes, as well as **shareware** themes, available on the Internet for all operating systems. It is also possible for users to create their own desktop themes. Microsoft used to require that users purchase an application called Microsoft Plus! to use desktop themes, but they included it as standard issue in Windows 98 and Windows Me. The initial release of Windows 2000 does not include the Plus! package (or its equivalent), although high customer demand leads some industry watchers to predict that the Plus! package will either be included in the next edition of Windows 2000, or be released separately (as it was for Windows 95). In Linux, the latest version of the KDE graphical desktop environment includes a tool to enable users to change their desktop theme.

development process

See “systems development method”

desktop

1) Using an office metaphor, a desktop is a computer display area that represents the kinds of objects one might find on a real desktop: documents, phonebook, telephone, reference sources, writing (and possibly drawing) tools, project folders. A desktop can be contained in a window that is part of the total display area or can be “full-screen” (the total display area). Conceivably, you can have multiple desktops (for different projects or work environments you may have) and switch among them.

In its Windows product, Microsoft provides what they call an Active Desktop. It includes representations of and access to desktop objects and also dynamic Web content as well, including integrated links to Web sites and information areas that are generated as the result of sites pushing requested information updates to the user.

2) Desktop is also an abbreviated form of *desktop computer*, a personal computer that fits on top of a desk.

device

1) In general, a device is a machine designed for a purpose. In a general context, a **computer** can be considered a device.

2) In the context of **computer** technology, a device is a unit of **hardware**, outside or inside the case or housing for the essential computer (processor, memory, and data paths) that is capable of providing input to the essential computer or of receiving output or of both. When the term is used generally (as in *computer devices*), it can include keyboards, mice, display monitors, hard disk drives, CD-ROM players, printers, audio speakers and microphones, and other hardware units. Some devices such as a hard disk drive or a CD-ROM drive, while physically inside the computer housing, are considered devices because they are separately installable and replaceable. With notebook and smaller computers, devices tend to be more physically integrated with the “non-device” part of the computer.

The units of a computer to which the term *device* is not applied include the **motherboard**, the main **processor** and additional processors such as numeric coprocessors, and random access memory (**RAM**).

The term **peripheral** (a truncation of *peripheral device*) is sometimes used as a synonym for *device* or any input/output unit.

device driver

A device driver is a **program** that controls a particular type of **device** that is attached to your computer. There are device **drivers** for printers, displays, CD-ROM readers, diskette drives, and so on. When you buy an **operating system**, many

device drivers are built into the product. However, if you later buy a new type of device that the operating system didn’t anticipate, you’ll have to install the new device driver. A device driver essentially converts the more general input/output instructions of the operating system to messages that the device type can understand.

Some Windows programs are **virtual device drivers**. These programs interface with the Windows Virtual Machine Manager. There is a virtual device driver for each main hardware device in the system, including the hard disk drive controller, keyboard, and serial and parallel ports. They’re used to maintain the status of a hardware device that has changeable settings. Virtual device drivers handle software **interrupts** from the system rather than hardware interrupts.

In Windows operating systems, a device driver file usually has a file name suffix of DLL or EXE. A virtual device driver usually has the suffix of VXD.

deviceCOM

DeviceCOM, from Intrinsic Software, is a line of device and network integration products that is used to make Internet or PC devices work with each other on a network. Developed to provide Distributed Component Object Model (**DCOM**) services for **Windows CE**, Microsoft’s embedded operating system for mobile devices, deviceCOM provides a development environment in which device-to-device communication is automatically managed so that application developers don’t have to write programs to handle it. DCOM provides a development framework for distributed applications; deviceCOM supplies a connectivity framework between Windows CE-based devices and an enterprise’s networked computers, through Microsoft’s Web solution platform.

DeviceCOM was created specifically for distributed embedded applications and is said to have a small **footprint** and flexible **protocol** support, and to be **fault-tolerant** and **firewall-friendly**. Available for either Windows or Linux operating systems, deviceCOM is currently being used in a number of products, including industrial automation, mobile computing, and point-of-sale applications.

Dialed Number Identification Service

DNIS (Dialed Number Identification Service) is a telephone service that identifies for the receiver of a call the number that the caller dialed. It's a common feature of 800 and 900 lines. If you have multiple 800 or 900 numbers to the same destination, DNIS tells which number was called. DNIS works by passing the touch tone digits (**dual tone multi frequency** or MF digits) to the destination where a special facility can read and display them or make them available for **call center** programming.

dial-up

Dial-up pertains to a telephone connection in a system of many lines shared by many users. A dial-up connection is established and maintained for a limited time duration. The alternative is a *dedicated* connection, which is continuously in place. Dial-up lines are sometimes called *switched* lines and dedicated lines are called *nonswitched* lines. A dedicated line is often a *leased line* that is rented from a telephone company.

A dial-up connection can be initiated manually or automatically by your computer's **modem** or other device.

dichotomizing search

See "binary search"

DICOM

DICOM (Digital Imaging and Communications in Medicine) is an application layer network protocol for the transmission of medical images, waveforms, and ancillary information. It was originally developed by the National Electrical Manufacturers Association (NEMA) and the American College of Radiology for CAT and MRI scan images. It is now controlled by the DICOM Standards Committee, and supports a wide range of medical images across the fields of radiology, cardiology, pathology and dentistry. DICOM uses TCP/IP as the lower-layer transport protocol.

DID

See "Direct Inward Dialing"

dielectric

See "dielectric material"

dielectric constant

The dielectric constant is the ratio of the **permittivity** of a substance to the permittivity of free space. It is an expression of the extent to which a material concentrates electric **flux**, and is the electrical equivalent of relative magnetic **permeability**.

As the dielectric constant increases, the electric flux density increases, if all other factors remain unchanged. This enables objects of a given size, such as sets of metal plates, to hold their electric charge for long periods of time, and/or to hold large quantities of charge. Materials with high dielectric constants are useful in the manufacture of high-value **capacitors**.

A high dielectric constant, in and of itself, is not necessarily desirable. Generally, substances with high dielectric constants break down more easily when subjected to intense electric fields, than do materials with low dielectric constants. For example, dry air has a low dielectric constant, but it makes an excellent dielectric material for capacitors used in high-power radio-frequency (**RF**) transmitters. Even if air does undergo dielectric breakdown (a condition in which the dielectric suddenly begins to conduct **current**), the breakdown is not permanent. When the excessive electric field is removed, air returns to its normal dielectric state. Solid dielectric substances such as polyethylene or glass, however, can sustain permanent damage.

Also see **dielectric**, **capacitor**, **electric field**, and **permittivity**.

dielectric material

A dielectric material is a substance that is a poor conductor of electricity, but an efficient supporter of **electrostatic fields**. If the flow of **current** between opposite electric charge poles is kept to a minimum while the electrostatic lines of flux are not impeded or interrupted, an electrostatic field can store energy. This property is useful in **capacitors**, especially at radio frequencies. Dielectric materials are also used in the construction of radio-frequency transmission lines.

In practice, most dielectric materials are solid. Examples include porcelain (ceramic), mica, glass, plastics, and the oxides of various metals. Some liquids and gases can serve as good dielectric materials. Dry air is an excellent dielectric, and is used in variable capacitors and some types of transmission lines. Distilled water is a fair dielectric. A vacuum is an exceptionally efficient dielectric.

An important property of a dielectric is its ability to support an electrostatic field while dissipating minimal energy in the form of heat. The lower the *dielectric loss* (the proportion of energy lost as heat), the more effective is a dielectric material. Another consideration is the *dielectric constant*, the extent to which a substance concentrates the electrostatic lines of flux. Substances with a low dielectric constant include a perfect vacuum, dry air, and most pure, dry gases such as helium and nitrogen. Materials with moderate dielectric constants include ceramics, distilled water, paper, mica, polyethylene, and glass. Metal oxides, in general, have high dielectric constants.

The prime asset of high-dielectric-constant substances, such as aluminum oxide, is the fact that they make possible the manufacture of high-value capacitors with small physical volume. But these materials are generally not able to withstand electrostatic fields as intense as low-dielectric-constant substances such as air. If the **voltage** across a dielectric material becomes too great—that is, if the electrostatic field becomes too intense—the material will suddenly begin to conduct current. This phenomenon is called *dielectric breakdown*. In components that use gases or liquids as the dielectric medium, this condition reverses itself if the voltage decreases below the critical point. But in components containing solid dielectrics, dielectric breakdown usually results in permanent damage.

Difference Engine

The Difference Engine, designed in the 1820s by the English mathematician and inventor **Charles Babbage**, was intended to automatically compute mathematical tables which, until that time, had been tediously calculated by hand and were prone to error. Babbage saw an opportunity to revolutionize the field.

With good political contacts and the ear of Prime Ministers, Babbage was able to acquire initial funding for the construction of his machine, a task expected to last 3 years. The project turned into a nightmare, however, as setbacks piled up. In 1827, family tragedies, including the death of his wife, led Babbage to escape in travels to the Continent. When he returned and eventually secured further funding, a personality clash with his head engineer, Joseph Clement, saw construction of the engine halted. In the meantime, Babbage had designed a general-purpose computer, the Analytical Engine. He sought funds to either complete the Difference Engine or commence his new Analytical Engine. By this stage, the 1840's, times were hard and a government which had already spent as much as 17,000 English pounds with little reward declined to continue financing his plans.

The Difference Engine was eventually built in 1991, the bicentennial of Babbage's birth, using the technology of the era as proof that Babbage's designs were valid. A working model resides today in the Science Museum in London.

Differentiated Services

Differentiated Services (DiffServ, or DS) is a **protocol** for specifying and controlling network traffic by class so that certain types of traffic get precedence—for example, voice traffic, which requires a relatively uninterrupted flow of data, might get precedence over other kinds of traffic. Differentiated Services is the most advanced method for managing traffic in terms of what is called Class of Service (CoS). Unlike the earlier mechanisms of 802.1p tagging and Type of Service (ToS), Differentiated Services avoids simple priority tagging and depends on more complex **policy** or rule statements to determine how to forward a given network **packet**. An analogy is made to travel services, in

which a person can choose among different modes of travel—train, bus, airplane—degree of comfort, the number of stops on the route, standby status, the time of day or period of year for the trip, and so forth. For a given set of packet travel rules, a packet is given one of 64 possible forwarding behaviors—known as per hop behaviors (PHBs). A six-bit field, known as the Differentiated Services Code Point (DSCP), in the Internet Protocol (IP) **header** specifies the per hop behavior for a given flow of packets.

Differentiated Services and the Class of Service approach provide a way to control traffic that is both more flexible and more **scalable** than the Quality of Service approach.

DiffServ

See “Differentiated Services”

digiboard

Digiboard or digicard is a generic name for a **serial port card** made by Digi International. While the typical PC comes with two serial ports, a compatible digiboard has the capability to add an additional four, eight, or 16 additional serial ports to a system.

A common use of a digiboard is to expand the services of a remote access server such as Microsoft RAS (Remote Access Server) for NT. It can also be used to expand a **terminal server** that accepts serial connections. Digiboards work with Windows, NetWare and most UNIX operating systems.

digicard

See “digiboard”

digital

Digital describes electronic technology that generates, stores, and processes data in terms of two states: positive and non-positive. Positive is expressed or represented by the number 1 and non-positive by the number 0. Thus, data transmitted or stored with digital technology is expressed as a string of 0's and 1's. Each of these state digits is referred to as a **bit** (and a string of bits that a computer can address individually as a group is a **byte**).

Prior to digital technology, electronic transmission was limited to **analog** technology, which conveys data as electronic signals of varying frequency or amplitude that are added to carrier waves of a given frequency. Broadcast and phone transmission has conventionally used analog technology.

Digital technology is primarily used with new physical communications media, such as *satellite* and **fiber optic** transmission. A **modem** is used to convert the digital information in your computer to analog signals for your phone line and to convert analog phone signals to digital information for your computer.

digital audio workstation

A digital audio workstation (DAW) is a computer that is specially equipped with a high-quality sound card and programming for editing and processing digital **audio** at a professional level. Digital audio workstations can range from a simple two-channel editor to a complete digital recording studio suite.

digital camera

A digital camera records and stores photographic images in digital form that can be fed to a computer as the impressions are recorded or stored in the camera for later loading into a computer. Currently, Kodak, Canon, and several other companies make digital cameras.

digital cash

Digital cash is a system of purchasing cash credits in relatively small amounts, storing the credits in your computer, and then spending them when making electronic purchases over the Internet. Theoretically, digital cash could be spent in very small increments, such as tenths of a cent (U.S.) or less. Most merchants accepting digital cash so far, however, use it as an alternative to other forms of payment for somewhat higher price purchases. There are several commercial approaches to digital cash on the Web.

Digital cash can also be stored on an electronically sensitive card. See **smart card** and **micropayment**.

digital certificate

A digital certificate is an electronic "credit card" that establishes your credentials when doing business or other transactions on the Web. It is issued by a certification authority (CA). It contains your name, a serial number, expiration dates, a copy of the certificate holder's **public key** (used for encrypting messages and **digital signatures**), and the digital signature of the certificate-issuing authority so that a recipient can verify that the certificate is real. Some digital certificates conform to a standard, X.509. Digital certificates can be kept in registries so that authenticating users can look up other users' public keys.

Digital Data Storage

Digital Data Storage (DDS) is a **format** for storing and backing up computer data on tape that evolved from the **Digital Audio Tape (DAT)** technology. DAT was created for CD-quality audio recording. In 1989, Sony and Hewlett Packard defined the DDS format for data storage using DAT tape cartridges. Tapes conforming to the DDS format can be played by either DAT or DDS tape drives. However, DDS tape drives cannot play DAT tapes since they can't pick up the audio on the DAT tape.

DDS uses a 4-mm tape. A DDS tape drive uses helical scanning for recording, the same process used by a video recorder (VCR). There are two read heads and two write heads. The read heads verify the data that has been written (recorded). If errors are present, the write heads rewrite the data. When restoring a backed-up file, the restoring software reads the directory of files located at the beginning of the tape, winds the tape to the location of the file, verifies the file, and writes the file onto the hard drive. DDS cannot update a backed-up file in the same place it was originally recorded. In general, DDS requires special software for managing the storage and retrieval of data from DDS tape drives.

There are four types of DDS drives:

- **DDS-1:** Stores up to 2 **gigabytes** of uncompressed data on a 120-minute cartridge.
- **DDS-2:** Stores up to 8 GB of data in compressed format on a 120-minute cartridge. DDS-2 is ideal for small network servers.
- **DDS-3:** Stores up to 24 GB of data on a 125-minute cartridge. The DDS-3 drive is ideal for medium-sized servers. DDS-3 uses PRML (Partial Response Maximum Likelihood). PRML eliminates electronic **noise** for a cleaner data recording.
- **DDS-4:** The newest DDS drive, DDS-4 stores up to 40 GB of data on a 125-minute cartridge. Small to mid-size businesses benefit from the DDS-4 drive. A DDS cartridge needs to be retired after 2,000 passes or 100 full backups. You should clean your DDS tape drive every 24 hours with a cleaning cartridge and discard the cleaning cartridge after 30 cleanings. DDS tapes have an expected life of at least 10 years.

digital divide

The term "digital divide" describes the fact that the world can be divided into people who do and people who don't have access to—and the capability to use—modern information technology, such as the telephone, television, or the Internet. The digital divide exists between those in cities and those in rural areas. For example, a 1999 study showed that 86% of Internet delivery was to the 20 largest cities. The digital divide also exists between the educated and the uneducated, between economic classes, and, globally, between the more and less industrially developed nations.

Digital Enhanced Cordless Telecommunications

See "DECT"

Digital Equipment Corporation

See "DEC"

Digital Imaging and Communications in Medicine

See "DICOM"

digital library

A digital library is a collection of documents in organized electronic form, available on the Internet or on **CD-ROM** (compact-disk read-only memory) disks. Depending on the specific library, a user may be able to access magazine articles, books, papers, images, sound files, and videos.

On the Internet, the use of a digital library is enhanced by a **broadband** connection such as cable modem or DSL. Dial-up connections can be used to access plain-text documents and some documents containing images, but for complex files and those with animated video content, a downstream data speed of at least several hundred kilobits per second (**Kbps**) can make the user's experience less tedious, as well as more informative. Internet-based digital libraries can be updated on a daily basis. This is one of the greatest assets of this emerging technology.

On CD-ROM, the amount of data is limited to several hundred megabytes (**MB**) per disk, but access is generally much faster than on an Internet connection. Several CD-ROMs can be combined in a set, and because the disks are small, a large library can be accommodated in a reasonable physical space. The main limitation of CD-ROM is the fact that updating cannot be done as frequently as on the Internet. In addition, producing and distributing CD-ROMs involves overhead costs that are largely nonexistent in Internet-based libraries.

Some institutions have begun the task of converting classic books to electronic format for distribution on the Internet. Some files can be viewed directly in **HTML** format; others can be downloaded in **PDF** format and printed. Some publishers keep electronic files of books and produce them one unit at a time in printed and bound form on demand.

Electronic distribution of intellectual and artistic property has authors, agents, and publishers concerned about the possibility of copyright infringement. It is much easier to copy a CD-ROM, or to download an electronic book and make unauthorized copies of it, than it is to reproduce bound volumes and distribute them illegitimately. Fundamental changes in copyright law—and/or changes in the way in which the laws are enforced—are likely to occur as digital libraries expand and their use becomes more widespread.

digital loop carrier

DLC also is an abbreviation for **Data Link Control**.

Digital loop carrier (DLC) is equipment that bundles a number of individual phone line signals into a single multiplexed **digital** signal for local traffic between a telephone company **central office** and a business complex or other outlying service area. Typically, up to 24 analog voice calls are combined into a single signal and transmitted over a single copper **T-carrier system** or **E-carrier** line, an optical fiber cable, or a wireless connection. In a home, business, or other installation using digital loop carrier, the **analog** phone lines of individual users are connected to a local DLC box which then converts the analog signals into digital and combines (multiplexes) them into one signal that is sent to the phone company's central office on the single line. At the central office, the combined signal is separated back into the original signals. An estimated 20% of today's telephone users are being served by digital loop carriers.

Digital loop carrier can carry traffic for regular phone calls (**plain old telephone service**) and Integrated Services Digital Network (**ISDN**) service. More recently, approaches have been developed for using DLC to handle the higher **bandwidth** of Digital Subscriber Line (**DSL**) service.

Digital loop carrier is typically used as an efficient way to provide service to an office building or complex and to extend service to new areas outside the current **local loop**. DLC is also used to set up telephone service in emergency situations. Customers can easily migrate from a T-1 or E-1 line to fiber optic when it becomes needed and is available.

digital object identifier

A digital object identifier (DOI) is a permanent identifier given to a Web file or other Internet document so that if its Internet address changes, users will be redirected to its new address. You submit a DOI to a centrally-managed directory and then use the address of that directory plus the DOI instead of a regular Internet address. The DOI system was conceived by the Association of American Publishers in partnership with the Corporation for National Research Initiatives and is now administered by the International DOI Foundation. Essentially, the DOI system is a scheme for Web page redirection by a central manager.

Initially, the only central directory is the one maintained by the DOI Foundation. It's envisioned, however, that other directories might be created and maintained, perhaps by each major industry. Here's what a typical DOI might look like: 10.1002/ISBNJ0-471-58064-3

In this example, the “10.1002” identifies the directory and the part after the “/” is the rest of the DOI—in this case, the ISBN number of a particular book that has been published. The “-3” indicates a specific part or chapter in the book.

The DOI would be associated with a specific Web page or **Uniform Resource Locator** in the directory. If you wanted to link to the document in a Web page, you would link to this URL:

<http://www.doi.org/10.1002/ISBNJ0-471-58064-3>

Here, “www.doi.org” happens to be the current and only directory manager. A user clicking on this link would be linking to the directory page which in turn would locate and send back the URL associated with the DOI. Assuming the directory was up-to-date, the page owner and the user could both be sure that the latest page would be returned.

Early users of the DOI system are principally major publishers with thousands of documents to keep track of, many available on the Web. Relocating files from time to time for such a large number of documents would require many link changes on the publisher’s site and perhaps a redirection page for users. With the DOI system, any future location change will require only updating the central directory and will not affect other site’s links (if they also use the DOI in their link).

digital photo album

A digital photo album is a software application that allows the user to import **image** files from a **digital camera**, **memory card**, **scanner**, or computer **hard disk** to a central **database**. Album software applications typically allow the user to view, sort, edit, label, and arrange photos by using a book-like **interface** that resembles a traditional photo album. Album applications often offer special features, such as providing the user with the ability to create slide shows, order prints and gift items, or receive free online storage space.

Many Internet service providers (**ISPs**), e-mail providers, and Web **portals** provide users with free tools to create and store online digital photo albums. Yahoo.com, for example, allows registered users 30MB for a digital photo album. Users do not need any special skills or software. After promising to use their digital photo album space in a manner that meets Yahoo community content standards, users click “upload” to place their **.gif** or **.jpeg** files in their photo album. Like most other online photo albums, Yahoo allows the album creator to choose whether to make their photo album public or keep it private. Public albums are given a universal resource locator (**URL**) address that users can share with others.

Smart frames are electronic picture frames that use universal plug and play (**UPnP**) to allow users to upload, exchange and print photos directly from their digital camera’s memory card. **Smart** frames are portable and provide an alternative to **browser**-based digital photo albums. Smart frames often have the same features that online albums have, making them a good alternative for users who want to view their digital photos but do not want to be limited to viewing them on a computer.

Digital Powerline

Digital Powerline (DPL) technology provides the transmission of data to users over the same lines that bring electric power to homes and businesses. Using the Internet’s **TCP/IP protocol**, companies using DPL across the mains electricity grid plan to deliver data at speeds up to 1 **Mbps**. DPL would allow a user to get Web pages and other Internet information over power lines with a 24-hour continuous connection (since your power lines are always connected). This would free your telephone for voice use. In addition, since many home appliances are attached to the power system, they could easily be addressed as Internet devices when plugged in.

NOR.WEB, a joint venture of Northern Telecom Limited (Nortel) and the UK-based United Utilities PLC, plans to offer a service to users in the UK. Trials of DPL are ongoing in Manchester, UK., and Milan, Italy. Utilities in Sweden and Germany have also shown interest and are planning trials.

The DPL technology has, however, been dogged by allegations that it has failed to overcome line noise on the power grid; in addition concerns have been addressed in certain countries that DPL will cause the power grid to emit unwanted radio frequency (**RF**) interference. NOR.WEB says, however, that their technology has overcome the line noise problem.

digital pulse wireless

See “ultra wideband radio”

digital rights management

Digital rights management (DRM) is a type of server software developed to enable secure distribution—and perhaps more importantly, to disable illegal distribution—of paid content over the Web. DRM technologies are being developed as a means of protection against the online piracy of commercially marketed material, which has proliferated through the widespread use of **Napster** and other **peer-to-peer** file exchange programs.

Although online content is protected by copyright laws, policing the Web and catching law-breakers is very difficult. DRM technology focuses on making it impossible to steal Web content in the first place, a much surer approach to the problem than the hit-and-miss strategies aimed at apprehending online poachers after the fact. A number of companies are releasing various DRM products based on a variety of approaches and technologies. In general, DRM products are turnkey packages that include everything needed for the operation, such as, for example, server software and user plug-ins.

A Brief Sampling of DRM Products:

ContentGuard (also the name of the company that sells it) DRM software uses XrML (Extensible Rights Markup Language), an XML-based language from Xerox's Palo Alto Research Center. Version 1.3 has four major components: a protection toolkit that allows users to decide on their own access and encryption rules, a distribution toolkit that helps users create interfaces for content distribution, a consumer toolkit that verifies authorization before content is distributed, and a **back-office** component that tracks usage and licensing.

InterTrust DRM, which is being developed by its own self-named company and British partner, Magex (of which Paul MacCartney is a prime investor), will focus on the protection of graphic and text content such as **JPEG**, **GIF**, and **PDF** files. The product will support a preview feature, as well as subscription capabilities.

EMediator DRM, from MediaDNA, works through a **plug-in** that users must download before they receive access to protected material. When the plug-in is downloaded, administrators can set various policies for access to different components of the content, such as print or copy restrictions set on material that may be freely viewed, or may set a time limit on access. Content sharing is disabled.

Vyou.com (pronounced *view dot com*) DRM software is made up of a mechanism (in this case called a *director*) that allows users to create their own policies regarding access, a server, and a protective plug-in that downloads automatically when a user attempts to download protected material.

digital signal processing

Digital signal processing (DSP) refers to various techniques for improving the accuracy and reliability of digital communications. Basically, DSP works by clarifying, or standardizing, the *levels* or *states* of a **digital** signal. A DSP circuit is able to differentiate between human-made signals, which are orderly, and **noise**, which is inherently chaotic.

All communications circuits contain some noise. This is true whether the signals are **analog** or digital, and regardless of the type of information conveyed. Noise is the eternal bane of communications engineers, who are always striving to find new ways to improve the **signal-to-noise ratio** in communications systems. Traditional methods of optimizing S/N ratio include increasing the transmitted signal power and increasing the receiver sensitivity. (In **wireless** systems, specialized antenna systems can also help.) Digital signal processing dramatically improves the sensitivity of a receiving unit. The effect is most noticeable when noise competes with a desired signal. A good DSP circuit can sometimes seem like an electronic miracle worker. But there are limits to what it can do. If the noise is so strong that all traces of the signal are obliterated, a DSP circuit cannot find any order in the chaos, and no signal will be received.

If an incoming signal is analog, for example a standard television broadcast station, the signal is first converted to digital form by an *analog-to-digital converter* (**ADC**). The resulting digital signal has two or more levels. Ideally, these levels are always predictable, exact voltages or currents. However, because the incoming signal contains noise, the levels are not always at the standard values. The DSP circuit adjusts the levels so they are at the correct values. This practically eliminates the noise. The digital signal is then converted back to analog form via a *digital-to-analog converter* (**DAC**).

If a received signal is digital, for example computer data, then the ADC and DAC are not necessary. The DSP acts directly on the incoming signal, eliminating irregularities caused by noise, and thereby minimizing the number of errors per unit time.

digital signal X

Digital signal X is a term for the series of standard digital transmission rates or levels based on DS0, a transmission rate of 64 **Kbps**, the **bandwidth** normally used channel. Both the North American **T-carrier system** and the European **E-carrier** systems of transmission operate using the DS series as a base multiple. The digital signal is what is carried inside the carrier system.

DS0 is the base for the digital signal X series. DS1, used as the signal in the T-1 carrier, is 24 DS0 (64 Kbps) signals transmitted using pulse-code modulation (**PCM**) and time-division multiplexing (**TDM**). DS2 is four DS1 signals multiplexed together to produce a rate of 6.312 **Mbps**. DS3, the signal in the T-3 carrier, carries a multiple of 28 DS1 signals or 672 DS0s or 44.736 Mbps.

Digital signal X is based on the **ANSI T1.107** guidelines. The **ITU-TS** guidelines differ somewhat. The following table summarizes the set of signals and relates them to the T-carrier and E-carrier systems.

Digital Signal Designator	Data Rate	DSn Multiple	T-Carrier	E-Carrier
DS0	64 Kbps	0	—	—
DS1	1.544 Mbps	24	T-1	—
—	2.048 Mbps	32	—	E1
DS1C	3.152 Mbps	48	—	—
DS2	6.312 Mbps	96	T-2	—
—	8.448 Mbps	128	—	E2
—	34.368 Mbps	512	—	E3
DS3	44.736 Mbps	672	T-3	—
—	139.264 Mbps	2048	—	E4
DS4/NA	139.264 Mbps	2176	—	—
DS4	274.176 Mbps	4032	—	—
—	565.148 Mbps	4 E4 channels	—	E5

digital signature legislation

See "Electronic Signatures in Global and National Commerce Act"

Digital Signature Standard

Digital Signature Standard (DSS) is the **digital signature algorithm** (DSA) developed by the U.S. National Security Agency (NSA) to generate a digital signature for the **authentication** of electronic documents. DSS was put forth by the National Institute of Standards and Technology (NIST) in 1994, and has become the U.S. government standard for authentication of electronic documents. DSS is specified in Federal Information Processing Standard (FIPS) 186.

DSA is a pair of large numbers that are computed according to the specified algorithm within parameters that enable the authentication of the signatory, and as a consequence, the **integrity** of the data attached. Digital signatures are generated through DSA, as well as verified. Signatures are generated in conjunction with the use of a **private key**; verification takes place in reference to a corresponding **public key**. Each signatory has their own paired public (assumed to be known to the general public) and private (known only to the user) keys. Because a signature can only be generated by an authorized person using their private key, the corresponding public key can be used by anyone to verify the signature.

A data summary of the information (called a *message digest*) is created through the use of a **hash function** (called the *Secure Hash Standard*, or *SHS*, and specified in FIPS 180). The data summary is used in conjunction with the DSA algorithm to create the digital signature that is sent with the message. Signature verification involves the use of the same hash function.

digital signature

A digital signature (not to be confused with a **digital certificate**) is an electronic signature that can be used to authenticate the identity of the sender of a message or the signer of a document, and possibly to ensure that the original content of the message or document that has been sent is unchanged. Digital signatures are easily transportable, cannot be imitated by someone else, and can be automatically time-stamped. The ability to ensure that the original signed message arrived means that the sender cannot easily repudiate it later.

A digital signature can be used with any kind of message, whether it is **encrypted** or not, simply so that the receiver can be sure of the sender's identity and that the message arrived intact. A digital certificate contains the digital signature of the certificate-issuing authority so that anyone can verify that the certificate is real.

How It Works

Assume you were going to send the draft of a contract to your lawyer in another town. You want to give your lawyer the assurance that it was unchanged from what you sent and that it is really from you.

1. You copy-and-paste the contract (it's a short one!) into an e-mail note.
2. Using special software, you obtain a message hash (mathematical summary) of the contract.
3. You then use a private key that you have previously obtained from a public-private key authority to encrypt the hash.
4. The encrypted hash becomes your digital signature of the message. (Note that it will be different each time you send a message.)

At the other end, your lawyer receives the message.

1. To make sure it's intact and from you, your lawyer makes a hash of the received message.
2. Your lawyer then uses your public key to decrypt the message hash or summary.
3. If the hashes match, the received message is valid.

Also see **hashing** and **Digital Signature Standard**.

Digital Silhouettes

Digital Silhouettes is the trademarked name that Predictive Networks has given to its complex but anonymous user profiles that are established through gathered **click stream** data and artificial intelligence (**AI**) processes. The profile is built from analysis of an individual's Web site visits, and classifies a user in over 140 demographic (such as "45-year-old suburban female") and content affinity areas (such as "garden enthusiast"). The selected demographics fall into the six major categories of gender, age, income, education, and race—all of which break down to subcategories. There are more than 90 content affinity subcategories, such as golf, pets, and car accessories, for example. Every time a user visits a Web site that is listed in an extensive Predictive Networks database, demographic and content characterization congruent with that site are added to the user's Digital Silhouette. The more Web sites the user visits, and the longer the user is monitored, the more refined the Digital Silhouette will become. Once the profile reaches a critical level of determined accuracy, the user may be sent marketing messages targeted to their Digital Silhouette.

Because of the volume and sensitivity of data gathered, privacy issues have been raised about Digital Silhouettes. Predictive Networks categorizes information with the capacity to identify individuals (such as names and addresses, for example) as Personally Identifiable Information (PII). The company claims that Digital Silhouettes are identified only by randomly assigned and anonymous ID numbers. Nevertheless, the idea that so much individual data is being collected makes many people uneasy; furthermore, some industry insiders believe that identifying information will, in some circumstances, be divulged.

Digital Subscriber Line

DSL (Digital Subscriber Line) is a technology for bringing high-**bandwidth** information to homes and small businesses over ordinary copper telephone lines. xDSL refers to different variations of DSL, such as ADSL, HDSL, and RADSL. Assuming your home or small business is close enough to a telephone company **central office** that offers DSL service, you may be able to receive data at rates up to 6.1 megabits (millions of bits) per second (of a theoretical 8.448 megabits per second), enabling continuous transmission of motion video, audio, and even 3-D effects. More typically, individual connections will provide from

1.544 **Mbps** to 512 Kbps downstream and about 128 Kbps upstream. A DSL line can carry both data and voice signals and the data part of the line is continuously connected. DSL installations began in 1998 and will continue at a greatly increased pace through the next decade in a number of communities in the U.S. and elsewhere. Compaq, Intel, and Microsoft working with telephone companies have developed a standard and easier-to-install form of ADSL called **G.Lite** that is accelerating deployment. DSL is expected to replace **ISDN** in many areas and to compete with the **cable modem** in bringing multimedia and 3-D to homes and small businesses.

Digital Subscriber Line Access Multiplexer

A Digital Subscriber Line Access Multiplexer (DSLAM) is a network device, usually at a telephone company central office, that receives signals from multiple customer Digital Subscriber Line (**DSL**) connections and puts the signals on a high-speed **backbone** line using **multiplexing** techniques. Depending on the product, DSLAM multiplexers connect DSL lines with some combination of asynchronous transfer mode (**ATM**), **frame relay**, or **Internet Protocol** networks. DSLAM enables a phone company to offer business or homes users the fastest phone line technology (DSL) with the fastest backbone network technology (ATM).

digital switch

A digital switch is a device that handles digital signals generated at or passed through a telephone company **central office** and forwards them across the company's **backbone** network. It receives the digital signals from the office's **channel banks** that have been converted from users' analog signals and switches them with other incoming signals out to the wide area network.

Digital switches are described in terms of classes based on the number of lines and features that are provided. A private branch exchange (**PBX**) is a digital switch owned by a private company. A **centrex** is a digital switch at the central office that manages switching for the private company from the central office.

digital television

Digital television (DTV) is the transmission of television signals using **digital** rather than conventional **analog** methods. Conventional standards—**National Television Standards Committee**, **Phase Alternation Line**, and **Sequential Couleur avec Memoire**—specify analog transmission. However, both the audio and video components of a television signal can be transmitted in **digital** form. Many engineers believe that DTV will become the industry standard within a few years.

V,W

X,Y,Z

Advantages of DTV over analog TV include:

- Superior image resolution (detail) for a given **bandwidth**
- Smaller bandwidth for a given image resolution
- Compatibility with computers and the Internet
- Interactivity
- Superior audio quality
- Consistency of reception over varying distances

Digital television is not the same thing as **HDTV** (high-definition television). HDTV describes a new television format (including a new aspect ratio and pixel size) but not how the format will be transmitted. HDTV can be transmitted in either analog or digital signals. However, since DTV technology is ideally suited for HDTV, it is likely that the names of the two technologies will continue to be used interchangeably.

digital versatile disc

DVD (digital versatile disc) is an optical disc technology that is expected to rapidly replace the **CD-ROM** disc (as well as the audio compact disc) over the next few years. The digital versatile disc (DVD) holds 4.7 **gigabytes** of information on one of its two sides, or enough for a 133-minute movie. With two layers on each of its two sides, it will hold up to 17 gigabytes of video, audio, or other information. (Compare this to the current CD-ROM disc of the same physical size, holding 600 **megabytes**. The DVD can hold more than 28 times as much information!)

DVD-Video is the usual name for the DVD format designed for full-length movies and is a box that will work with your television set. DVD-ROM is the name of the player that will (sooner or later) replace your computer's CD-ROM. It will play regular CD-ROM discs as well as DVD-ROM discs. DVD-RAM is the writeable version. DVD-Audio is a player designed to replace your compact disc player.

DVD uses the **MPEG-2** file and compression standard. MPEG-2 images have four times the resolution of MPEG-1 images and can be delivered at 60 interlaced fields per second where two fields constitute one image frame. (MPEG-1 can deliver 30 noninterlaced frames per second.) Audio quality on DVD is comparable to that of current audio compact discs.

digital video

Digital video is part of digital versatile disc (**DVD**), a new optical disc technology that is expected to rapidly replace the **CD-ROM** over the next few years. The DVD holds 4.7 **gigabytes** of information on one of its two sides, or enough for a 133-minute movie. With two layers on each of its two sides, it will hold up to 17 gigabytes of video, audio, or other information. (Compare this to the current CD-ROM disc of the same physical size, holding 600 **megabytes**. The DVD can hold more than 28 times as much information.)

The DVD player will also play regular CD-ROM discs. DVDs can be recorded in any of three formats, variously optimized for: video (for example, continuous movies) audio (for example, long-playing music), or a mixture (for example, interactive multimedia presentations). The DVD drive has a transfer rate somewhat faster than an eight-speed CD-ROM player.

DVD uses the **MPEG-2** file and compression standard. MPEG-2 images have four times the resolution of MPEG-1 images and can be delivered at 60 interlaced fields per second where two fields constitute one image frame. (MPEG-1 can deliver 30 noninterlaced frames per second.) Audio quality on DVD is comparable to that of current audio compact discs.

Digital Video Broadcasting

Digital Video Broadcasting (DVB) is a set of standards that define digital broadcasting using existing satellite, cable, and terrestrial infrastructures. In the early 1990s, European broadcasters, consumer equipment manufacturers, and regulatory bodies formed the European Launching Group (ELG) to discuss introducing **digital television** (DTV) throughout Europe. Today, the DVB Project consists of over 220 organizations in more than 29 countries worldwide. DVB-compliant digital broadcasting and equipment is widely available and is distinguished by the DVB logo. Numerous DVB broadcast services are available in Europe, North and South America, Africa, Asia, and Australia. The term *digital television* is sometimes used as a synonym for DVB. However, the Advanced Television Systems Committee (**ATSC**) standard is the digital broadcasting standard used in the U.S.

A fundamental decision of the DVB Project was the selection of **MPEG-2**, one of a series of **MPEG standards** for **compression** of audio and video signals. MPEG-2 reduces a single signal from 166 Mbits to 5 Mbits allowing broadcasters to transmit digital signals using existing cable, satellite, and terrestrial systems. MPEG-2 uses the **lossy compression** method, which means that the digital signal sent to the television is compressed and some data is lost. This lost data does not affect how the human eye perceives the picture. Two digital television formats that use MPEG-2 compression are standard definition television (**SDTV**) and high definition television (**HDTV**). SDTV's picture and sound quality is similar to digital versatile disc (**DVD**). HDTV programming presents five times as much information to the eye than SDTV, resulting in cinema-quality programming.

DVB uses **conditional access** (CA) systems to prevent external piracy. There are numerous CA systems available to content providers allowing them to choose the CA system that they feel is adequate for the services they provide. Each CA system provides a security module that scrambles and encrypts data. This security module is embedded within the receiver or is detachable in the form of a **PC card**. Inside the

receiver, there is a **smart card** that contains the user's access information. The following describes the conditional access process:

- The receiver receives the digital data stream.
- The data flows into the conditional access module, which contains the content provider's unscrambling **algorithms**.
- The conditional access module verifies the existence of a smart card that contains the subscriber's authorization code.
- If the authorization code is accepted, the conditional access module unscrambles the data and returns the data to the receiver. If the code is not accepted, the data remains scrambled restricting access.
- The receiver then decodes the data and outputs it for viewing.

For years, smart cards have been used for pay TV programming. Smart cards are inexpensive allowing the content provider to issue updated smart cards periodically to prevent piracy. Detachable PC cards allow subscribers to use DVB services anywhere DVB technology is supported.

DVB is an **open** system as opposed to a closed system. Closed systems are content provider-specific, not expandable, and optimized only for television. Open systems such as DVB allows the subscriber to choose different content providers and allows integration of PCs and televisions. DVB systems are optimized for not only television but also for home shopping and banking, private network broadcasting, and interactive viewing. DVB offers the future possibilities of providing high-quality television display in buses, cars, trains, and hand-held devices. DVB allows content providers to offer their services anywhere DVB is supported regardless of geographic location, expand their services easily and inexpensively, and ensure restricted access to subscribers, thus reducing lost revenue due to unauthorized viewing.

Digital-Advanced Mobile Phone Service

See "D-AMPS"

digital-to-analog conversion

Digital-to-analog conversion is a process in which signals having a few (usually two) defined levels or states (**digital**) are converted into signals having a theoretically infinite number of states (**analog**). A common example is the processing, by a **modem**, of computer data into audio-frequency (AF) tones that can be transmitted over a **twisted pair** telephone line. The circuit that performs this function is a *digital-to-analog converter (DAC)*.

Basically, digital-to-analog conversion is the opposite of **analog-to-digital conversion**. In most cases, if an *analog-to-digital converter (ADC)* is placed in a communications circuit after a DAC, the digital signal output is identical to the

digital signal input. Also, in most instances when a DAC is placed after an ADC, the analog signal output is identical to the analog signal input.

Binary digital impulses, all by themselves, appear as long strings of ones and zeros, and have no apparent meaning to a human observer. But when a DAC is used to decode the binary digital signals, meaningful output appears. This might be a voice, a picture, a musical tune, or mechanical motion.

Both the DAC and the ADC are of significance in some applications of **digital signal processing**. The intelligibility or fidelity of an analog signal can often be improved by converting the analog input to digital form using a DAC, then clarifying the digital signal, and finally converting the "cleaned-up" digital impulses back to analog form using an ADC.

DIMM

A DIMM (dual in-line memory module) is a double **SIMM** (single in-line memory module). Like a SIMM, it's a **module** containing one or several random access **memory (RAM)** chips on a small circuit board with pins that connect it to the computer **motherboard**. A SIMM typically has a 32 data bit (36 bits counting **parity** bits) path to the computer that requires a 72-pin connector. For synchronous dynamic RAM (**SDRAM**) chips, which have a 64 data bit connection to the computer, SIMMs must be installed in in-line pairs (since each supports a 32-bit path). A single DIMM can be used instead. A DIMM has a 168-pin connector and supports 64-bit data transfer.

diode

A diode is a specialized electronic component with two electrodes called the *anode* and the *cathode*. Most diodes are made with **semiconductor** materials such as silicon, germanium, or selenium. Some diodes are comprised of metal electrodes in a chamber evacuated or filled with a pure elemental gas at low pressure. Diodes can be used as rectifiers, signal limiters, voltage regulators, **switches**, signal modulators, signal mixers, signal demodulators, and **oscillators**.

The fundamental property of a diode is its tendency to conduct electric **current** in only one direction. When the cathode is negatively charged relative to the anode at a **voltage** greater than a certain minimum called *forward breakover*, then current flows through the diode. If the cathode is positive with respect to the anode, is at the same voltage as the anode, or is negative by an amount less than the forward breakover voltage, then the diode does not conduct current. This is a simplistic view, but is true for diodes operating as rectifiers, switches, and limiters. The forward breakover voltage is approximately six tenths of a volt (0.6 V) for silicon devices, 0.3 V for germanium devices, and 1 V for selenium devices.

The above general rule notwithstanding, if the cathode voltage is positive relative to the anode voltage by a great enough amount, the diode will conduct current. The voltage required to produce this phenomenon, known as the *avalanche voltage*, varies greatly depending on the nature of the semiconductor material from which the device is fabricated. The avalanche voltage can range from a few volts up to several hundred volts.

When an **analog** signal passes through a diode operating at or near its forward breakover point, the signal waveform is distorted. This *nonlinearity* allows for modulation, demodulation, and signal mixing. In addition, signals are generated at *harmonics*, or integral multiples of the input **frequency**. Some diodes also have a characteristic that is imprecisely termed *negative resistance*. Diodes of this type, with the application of a voltage at the correct level and the polarity, generate analog signals at microwave radio frequencies.

Semiconductor diodes can be designed to produce direct current (**DC**) when visible light, **infrared transmission** (IR), or ultraviolet (UV) energy strikes them. These diodes are known as *photovoltaic cells* and are the basis for solar electric energy systems and photosensors. Yet another form of diode, commonly used in electronic and computer equipment, emits visible light or IR energy when current passes through it. Such a device is the familiar *light-emitting diode* (LED).

dipole antenna

A dipole antenna is a straight electrical conductor measuring $\frac{1}{2}$ **wavelength** from end to end and connected at the center to a radio-frequency (**RF**) **feed line**. This antenna, also called a *doublet*, is one of the simplest types of **antennas**, and constitutes the main RF radiating and receiving element in various sophisticated types of antennas. The dipole is inherently a balanced antenna, because it is bilaterally symmetrical.

Ideally, a dipole antenna is fed with a balanced, parallel-wire RF transmission line. However, this type of line is not common. An unbalanced feed line, such as **coaxial cable**, can be used, but to ensure optimum RF **current** distribution on the antenna element and in the feed line, an RF transformer called a *balun* (contraction of the words "balanced" and "unbalanced") should be inserted in the system at the point where the feed line joins the antenna. For best performance, a dipole antenna should be more than $\frac{1}{2}$ wavelength above the ground, the surface of a body of water, or other horizontal, conducting medium such as sheet metal roofing. The element should also be at least several wavelengths away from electrically conducting obstructions such as supporting towers, utility wires, guy wires, and other antennas.

Dipole antennas can be oriented horizontally, vertically, or at a slant. The polarization of the **electromagnetic field** (EM) radiated by a dipole transmitting antenna corresponds to the

orientation of the element. When the antenna is used to receive RF signals, it is most sensitive to EM fields whose polarization is parallel to the orientation of the element. The RF current in a dipole is maximum at the center (the point where the feed line joins the element), and is minimum at the ends of the element. The RF **voltage** is maximum at the ends and is minimum at the center.

direct access storage device

See "DASD"

direct access

In computer storage, direct access is the ability to obtain data from a storage device by going directly to where it is physically located on the device rather than by having to sequentially look for the data at one physical location after another. A direct access storage device (**DASD**) has the electrical or electromechanical means to be immediately positioned for reading and writing at any addressable location on the device.

An alternative to direct access is **sequential access**, in which a data location is found by starting at one place and seeking through every successive location until the data is found. Historically, **tape storage** is associated with sequential access, and **disk storage** is associated with direct access.

direct current

See "DC"

Direct Inward Dialing

Direct Inward Dialing (DID) is a service of a local phone company (or **local exchange carrier**) that provides a block of telephone numbers for calling into a company's **private branch exchange** (PBX) system. Using DID, a company can offer its customers individual phone numbers for each person or workstation within the company without requiring a physical line into the PBX for each possible connection.

For example, a company might rent 100 phone numbers from the phone company that could be called over eight physical telephone lines (these are called "trunk lines"). This would allow up to eight ongoing calls at a time; additional inbound calls would get a busy signal until one of the calls completed or be able to leave a voice mail message. The PBX automatically switches a call for a given phone number to the appropriate workstation in the company. A PBX switchboard operator is not involved.

A DID system can be used for **fax** and voice mail as well as for live voice connections. Compared to regular PBX service, DID saves the cost of a switchboard operator, calls go through faster, and callers feel they are calling a person rather than a company.

Direct Memory Access

Direct Memory Access (DMA) is a capability provided by some computer **bus** architectures that allows **data** to be sent directly from an attached device (such as a disk drive) to the **memory** on the computer's **motherboard**. The **micro-processor** is freed from involvement with the data transfer, thus speeding up overall computer operation.

Usually a specified portion of memory is designated as an area to be used for direct memory access. In the **ISA** bus standard, up to 16 megabytes of memory can be addressed for DMA. The **EISA** and **Micro Channel Architecture** standards allow access to the full range of memory addresses (assuming they're addressable with 32 bits). **Peripheral Component Interconnect** accomplishes DMA by using a **bus master** (with the microprocessor "delegating" I/O control to the PCI controller).

An alternative to DMA is the Programmed Input/Output (PIO) interface in which all data transmitted between devices goes through the processor. A newer protocol for the ATA/IDE interface is **Ultra DMA**, which provides a **burst** data transfer rate up to 33 MB (megabytes) per second.

Direct Rambus

See "DRDRAM"

direct sequence spread spectrum

Direct sequence spread spectrum, also known as direct sequence code division multiple access (DS-CDMA), is one of two approaches to **spread spectrum modulation** for digital signal transmission over the airwaves. In direct sequence spread spectrum, the stream of information to be transmitted is divided into small pieces, each of which is allocated across to a frequency channel across the spectrum. A data signal at the point of transmission is combined with a higher data-rate bit sequence (also known as a *chipping code*) that divides the data according to a spreading ratio. The redundant chipping code helps the signal resist interference and also enables the original data to be recovered if data bits are damaged during transmission.

Direct sequence contrasts with the other spread spectrum process, known as frequency hopping spread spectrum, or frequency hopping code division multiple access (**FH-CDMA**), in which a broad slice of the bandwidth spectrum is divided into many possible broadcast frequencies. In general, frequency-hopping devices use less power and are cheaper, but the performance of DS-CDMA systems is usually better and more reliable.

Spread spectrum first was developed for use by the military because it uses wideband signals that are difficult to detect and that resist attempts at jamming. In recent years, researchers have turned their attention to applying spread spectrum processes for commercial purposes, especially in local area wireless networks.

directory

A directory is, in general, an approach to organizing information, the most familiar example being a telephone directory.

1) On the World Wide Web, a directory is a subject guide, typically organized by major topics and subtopics. The best-known directory is the one at Yahoo (<http://www.yahoo.com>). Many other sites now use a Yahoo-like directory including major **portal** sites.

2) In computer file systems, a directory is a named group of related **files** that are separated by the naming convention from other groups of files.

3) In computer networks, a directory is a collection of users, user passwords, and, usually, information about what network resources they can access.

Directory Services Markup Language

See "DSML"

Directory-Enabled Networking

See "DEN"

DirectX

DirectX is an application program interface (API) for creating and managing graphic images and multimedia effects in **applications** such as games or active Web pages that will run in Microsoft's Windows **operating systems**. (Such an application program might be written in **C++**, or Visual C/C++, or **Java**.) The capability to "play" DirectX applications comes as an integrated part of Microsoft's Internet Explorer Web **browser**. (A 3-D player is optionally downloadable.)

The DirectX Software Development Kit (SDK) includes tools that let a developer create or integrate graphic images, overlays, **sprites**, and other game elements, including sound. There is also a Driver Development Kit (DDK) that lets developers create **drivers** for display, audio, and other I/O devices.

DirectX is part of Microsoft's larger vision of an **object-oriented** development environment. For example, a sprite is created as an instance of a sprite **class**. Developers can also take advantage of Microsoft's set of prepackaged routines or small programs that are part of the **Microsoft Foundation Class Library**.

DirectX is designed so that some functions can be performed on a graphics accelerator **card**, freeing the microprocessor for other work. The accelerator manufacturer provides a **driver** especially for DirectX.

DirectX consists of five components:

- DirectDraw, an interface that lets you define two-dimensional images, specify textures, and manage double buffers (a technique for changing images)
- Direct3D, an interface for creating three-dimensional images
- DirectSound, an interface for integrating and coordinating sound with the images
- DirectPlay, a plug-in for end users, is also used by developers to test their application
- DirectInput, an interface for input from I/O devices

DirXML

DirXML is Novell's directory interchange software that uses XML to keep different directories synchronized. With DirXML, an IT manager can administer multiple user databases from a single interface, using Novell Directory Services (NDS) eDirectory to replicate the information. DirXML works within an existing network infrastructure and integrates NDS with directories in Microsoft Exchange, Lotus Notes, Windows 2000 Active Directory, and others.

As data flows into DirXML, it is translated into XML. The data is also converted into the target directory's native data format.

Novell is the first software vendor to utilize XML as the key language for directory schema publishing, data interchange, and query. Using DirXML, a company only has to enter information once and it will be identically replicated across its entire network. For instance, should a company insert address changes into a customer service database, those changes will automatically appear in its billing, shipping, and marketing directories. Thus, DirXML reduces manual labor costs, minimizes the possibility for human error, and saves in redundant data management expenses.

DirXML supports Windows 2000, Windows NT, Sun Solaris, NetWare, and Linux. Novell plans to add support for UNIX Tru64.

disaster recovery plan

A disaster recovery plan (DRP)—sometimes referred to as a Business Continuity Plan (BCP) or Business Process Contingency Plan (BPCP)—describes how an organization is to deal with potential disasters. Just as a disaster is an event that makes the continuation of normal functions impossible, a disaster recovery plan consists of the precautions taken so that the effects of a disaster will be minimized, and the organization will be able to either maintain or quickly resume mission-critical functions. Typically, disaster recovery planning involves an analysis of business processes and continuity needs; it may also include a significant focus on disaster prevention.

Disaster recovery is becoming an increasingly important aspect of enterprise computing. As devices, systems, and networks become ever more complex, there are simply more

things that can go wrong. As a consequence, recovery plans have also become more complex. According to Jon William Toigo (the author of *Disaster Recovery Planning*), fifteen years ago a disaster recovery plan might consist of powering down a mainframe and other computers in advance of a threat (such as a fire, for example, or the sprinkler system), disassembling components, and subsequently drying circuit boards in the parking lot with a hair dryer. Current enterprise systems tend to be too complicated for such simple and hands-on approaches, however, and interruption of service or loss of data can have serious financial impact, whether directly or through loss of customer confidence.

Appropriate plans vary a great from one enterprise to another, depending on variables such as the type of business, the processes involved, and the level of security needed. Disaster recovery planning may be developed within an organization or purchased as a software application or a service. It is not unusual for an enterprise to spend 25% of its Information Technology (IT) budget on disaster recovery.

disaster recovery planning

See "disaster recovery plan"

discrete

Discrete (pronounced dihs-KREET, from the Latin *discretus* and perhaps *discernere*, meaning to separate) is an adjective meaning separate and distinct. *Discretion* and *discreet* derive from the same origin and have to do with the use of separate or individual judgement.

discrete multitone

Discrete multitone (DMT) is a method of separating a Digital Subscriber Line (DSL) signal so that the usable frequency range is separated into 256 frequency bands (or channels) of 4.3125 KHz each. DMT uses the fast Fourier transform (FFT) algorithm for modulation and demodulation. Dividing the frequency spectrum into multiple channels allows DMT to work better when AM radio transmitters are present. Within each channel, modulation uses quadrature amplitude modulation (QAM). By varying the number of bits per symbol within a channel, the modem can be rate-adaptive. Both G.DMT and G.Lite use DMT.

Other modulation technologies for DSL are carrierless amplitude modulation (CAP) and multiple virtual line (MVL). However, DMT is the most widely used and appears to be becoming the industry standard.

discussion board

A discussion board is a general term for any online "bulletin board" where you can leave and expect to see responses to messages you have left. Or you can just read the board. Bulletin board services were invented for this purpose (as

well as to allow for the exchange of uploaded/downloaded files). On the Internet, **Usenet** provides thousands of discussion boards. Discussion board software is now available that allows discussion boards to be added to a Web site.

dish antenna

A dish antenna, also known simply as a *dish*, is common in **microwave** systems. This type of antenna can be used for **satellite** communication and broadcast reception, space communications, radio astronomy, and radar.

A dish antenna consists of an active, or driven, element and a passive parabolic or spherical reflector. The driven element can be a **dipole antenna** or a **horn antenna**. If a horn is used, it is aimed back at the center of the reflecting dish. The reflector has a diameter of at least several **wavelengths**. As the wavelength increases (and the **frequency** decreases), the minimum required dish diameter becomes larger.

When the dipole or horn is properly positioned and aimed, incoming **electromagnetic fields** bounce off the reflector, and the energy converges on the driven element. If the horn or dipole is connected to a transmitter, the element emits electromagnetic waves that bounce off the reflector and propagate outward in a narrow beam.

A dish antenna is usually operated with an unbalanced **feed line**. For satellite television reception, **coaxial cable** is used. In applications such as radar where a high-power signal is transmitted, a feed system is preferred.

disintermediation

Disintermediation is giving the user or the consumer direct access to information that otherwise would require a mediator, such as a salesperson, a librarian, or a lawyer. Observers of the Internet and the World Wide Web note that these new technologies give users the power to look up medical, legal, travel, or comparative product information directly, in some cases removing the need for the mediator (doctor, lawyer, salesperson) or at the very least changing the relationship between the user and the product or service provider.

Also see **antidisintermediation**.

disk

See "diskette"

disk cache

A disk cache is a mechanism for improving the time it takes to read from or write to a **hard disk**. Today, the disk cache is usually included as part of the hard disk. A disk cache can also be a specified portion of random access memory (**RAM**). The disk cache holds data that has recently been

read and, in some cases, adjacent data areas that are likely to be accessed next. Write caching is also provided with some disk caches.

The other type of hardware cache inside your computer is **cache memory**. Also see **cache**.

Disk Operating System

See "DOS"

disk striping

In computers that use multiple hard disk systems, disk striping is the process of dividing a body of data into blocks and spreading the data blocks across several **partitions** on several **hard disks**. Each stripe is the size of the smallest partition. For example, if three partitions are selected with one partition equaling 150 **megabytes**, another 100MB, and the third 50MB, each stripe will be 50 MB in size. It is wise to create the partitions equal in size to prevent wasting disk space. Each stripe created is part of the stripe set. Disk striping is used with redundant array of independent disks (**RAID**). RAID is a storage system that uses multiple disks to store and distribute data. Up to 32 hard disks can be used with disk striping.

There are two types of disk striping: single user and multi-user. Single user disk striping allows multiple hard disks to simultaneously service multiple **I/O** requests from a single workstation. Multi-user disk striping allows multiple **I/O** requests from several workstations to be sent to multiple hard disks. This means that while one hard disk is servicing a request from a workstation, another hard disk is handling a separate request from a different workstation.

Disk striping is used with or without **parity**. When disk striping is used with parity, an additional stripe that contains the parity information is stored on its own partition and hard disk. If a hard disk fails, a fault tolerance driver makes the lost partition invisible allowing reading and writing operations to continue which provides time to create a new stripe set. Once a hard disk fails, the stripe set is no longer fault tolerant, which means that if one or more hard disks fail after the first one, the stripe set is lost. Disk striping without parity provides no fault tolerance. The disk striping process is used in conjunction with software that lets the user know when a disk has failed. This software also allows the user to define the size of the stripes, the color assigned to the stripe set for recognition and diagnosing, and whether parity was used or not.

diskette

A diskette is a random access, removable data storage medium that can be used with personal computers. The term usually refers to the magnetic medium housed in a rigid plastic cartridge measuring 3.5 inches square and about 2 millimeters thick. Also called a "3.5-inch diskette," it can store up to 1.44 megabytes (MB) of data. Although most

personal computers today come with a 3.5-inch diskette drive pre-installed, some **network computers** now omit them.

Some older computers provide drives for magnetic diskettes that are 5.25 inches square, about 1 millimeter thick, and capable of holding 1.2 megabytes of data. These were sometimes called “floppy disks” or “floppies” because their housings are flexible. In recent years, 5.25-inch diskettes have been largely replaced by 3.5-inch diskettes, which are physically more rugged. Many people also call the newer hard-cased diskette a “floppy.”

Magnetic diskettes are convenient for storing individual files and small programs. However, the **magneto-optical diskette** is more popular for mass storage, backup, and archiving. An MO diskette is only a little larger, physically, than a conventional 3.5-inch magnetic diskette. But because of the sophisticated read/write technology, the MO diskette can store many times more data.

displacement

Displacement (symbolized d or s), also called length or distance, is a one-dimensional quantity representing the separation between two defined points. The standard unit of displacement in the International System of Units (SI) is the **meter** (m).

Displacement is usually measured or defined along a straight line. For example, we might speak of the distance between the center of the earth and an orbiting **satellite**, and measure it as 13,000,000 meters. However, displacement is sometimes measured or defined along curved paths. The most common example is in expressions of the distance between geographic locations on the earth's surface; the equator is approximately 10,000,000 meters from the North Pole, for example. Other examples of nonlinear displacement include the circumference of a subatomic particle, the actual length (as opposed to the straight span) of a sagging rope, or the length of wire that comprises a coil.

When expressing large or small distances, **prefix multipliers** are attached to the meter. The table below shows the most common alternative displacement units and their relationship to the meter.

Unit (and symbol)	To convert to meters, multiply by:	Conversely, multiply by:
kilometer (km)	1000	0.001
centimeter (cm)	0.01	100
millimeter (mm)	0.001	1000
micrometer or micron (μ)	10^{-6}	10^6
nanometer (nm)	10^{-9}	10^9
Ångström (Å)	10^{-10}	10^{10}

Compare **area**, and **volume**.

Also see **centimeter**, **meter**, **meter squared**, **meter cubed**, and International System of Units (SI).

display

A display is a computer output surface and projecting mechanism that shows text and often graphic images to the computer user, using a cathode ray tube (CRT), liquid crystal display (LCD), light-emitting diode, gas plasma, or other image projection technology. The display is usually considered to include the **screen** or projection surface and the device that produces the information on the screen. In some computers, the display is packaged in a separate unit called a **monitor**. In other computers, the display is integrated into a unit with the processor and other parts of the computer. (Some sources make the distinction that the monitor includes other signal-handling devices that feed and control the display or projection device. However, this distinction disappears when all these parts become integrated into a total unit, as in the case of notebook computers.) Displays (and monitors) are also sometimes called *video display terminals (VDTs)*. The terms *display* and *monitor* are often used interchangeably.

Most computer displays use **analog** signals as input to the display image creation mechanism. This requirement and the need to continually refresh the display image mean that the computer also needs a display or **video adapter**. The video adapter takes the **digital** data sent by application programs, stores it in video random access memory (**video RAM**), and converts it to analog data for the display scanning mechanism using an digital-to-analog converter (DAC).

Displays can be characterized according to:

- Color capability
- Sharpness and viewability
- The size of the screen
- The projection technology

Color Capability

Today, most desktop displays provide color. Notebook and smaller computers sometimes have a less expensive *monochrome* display. Displays can usually operate in one of several **display modes** that determine how many bits are used to describe color and how many colors can be displayed. A display that can operate in SuperVGA mode can display up to 16,777,216 colors because it can process a 24-bit long description of a **pixel**. The number of bits used to describe a pixel is known as its *bit-depth*. The 24-bit bit-depth is also known as **true color**. It allows eight bits for each of the three additive primary colors—red, green, and blue. Although human beings can't really distinguish that many colors, the 24-bit system is convenient for graphic designers since it allocates one byte for each color. The Visual Graphics

Array (VGA) mode is the lowest common denominator of display modes. Depending on the resolution setting, it can provide up to 256 colors.

Sharpness and Viewability

The absolute physical limitation on the potential image sharpness of a screen image is the **dot pitch**, which is the size of an individual beam that gets through to light up a point of phosphor on the screen. (The shape of this beam can be round or a vertical, slot-shaped rectangle depending on the display technology.) Displays typically come with a dot pitch of .28 mm (millimeters) or smaller. The smaller the dot pitch in millimeters, the greater the potential image sharpness.

The actual sharpness of any particular overall display image is measured in dots-per-inch (**dpi**). The dots-per-inch is determined by a combination of the screen **resolution** (how many **pixels** are projected on the screen horizontally and vertically) and the physical screen size. The same resolution spread out over a larger screen offers reduced sharpness. On the other hand, a high-resolution setting on a smaller surface will product a sharper image, but text readability will become more difficult.

Viewability includes the ability to see the screen image well from different angles. Displays with cathode ray tubes (CRT) generally provide good viewability from angles other than straight on. Flat-panel displays, including those using light-emitting diode and liquid crystal display technology, are often harder to see at angles other than straight on.

The Size of the Screen

On desktop computers, the display screen width relative to height, known as the *aspect ratio*, is generally standardized at 4 to 3 (usually indicated as "4:3"). Screen sizes are measured in either millimeters or inches diagonally from one corner to the opposite corner. Popular desktop screen sizes are 12-, 13-, 15-, and 17-inch. Notebook screen sizes are somewhat smaller.

The Projection Technology

Most displays in current use employ cathode ray tube (CRT) technology similar to that used in most television sets. The CRT technology requires a certain distance from the beam projection device to the screen in order to function. Using other technologies, displays can be much thinner and are known as *flat-panel displays*. Flat panel display technologies include light-emitting diode (LED), liquid crystal display (LCD), and gas plasma. LED and gas plasma work by lighting up display screen positions based on the voltages at different grid intersections. LCDs work by blocking light rather than creating it. LCDs require far less energy than LED and gas plasma technologies and are currently the primary technology for notebook and other mobile computers.

Displays generally handle data input as **character** maps or **bitmaps**. In character-mapping mode, a display has a preallocated amount of pixel space for each character. In bitmap mode, it receives an exact representation of the screen image that is to be projected in the form of a sequence of bits that describe the color values for specific **x and y coordinates** starting from a given location on the screen. Displays that handle bitmaps are also known as *all-points addressable* displays.

display modes

Displays for personal computers have steadily improved since the days of the monochrome monitors that were used in word processors and text-based computer systems in the 1970s. In 1981, IBM introduced the Color Graphics Adapter (CGA). This display system was capable of rendering four colors, and had a maximum **resolution** of 320 **pixels** horizontally by 200 pixels vertically. While CGA was all right for simple computer games such as solitaire and checkers, it did not offer sufficient image resolution for extended sessions of word processing, desktop publishing, or sophisticated graphics applications.

In 1984, IBM introduced the Enhanced Graphics Adapter (EGA) display. It allowed up to 16 different colors and improved the resolution to 640 pixels horizontally by 350 pixels vertically. This improved the appearance of the display and made it possible to read text more easily than with CGA. Nevertheless, EGA did not offer sufficient image resolution for high-level applications such as graphic design and desktop publishing.

In 1987, IBM introduced the Video Graphics Array (VGA) display system. This has become the accepted minimum standard for PC clones. Many VGA monitors are still in use today. The maximum resolution depends on the number of colors displayed. You can choose between 16 colors at 640 × 480 pixels, or 256 colors at 320 × 200 pixels. All IBM-compatible computers support the VGA standard.

In 1990, IBM introduced the Extended Graphics Array (XGA) display as a successor to its 8514/A display. A later version, XGA-2 offers 800 by 600 pixel resolution in **true color** (16 million colors) and 1,024 by 768 resolution in 65,536 colors.

Most PC displays sold today are described as Super Video Graphics Array (SVGA) displays. SVGA originally just meant "beyond "VGA" and was not a single standard. More recently, the Video Electronics Standards Association (VESA) has established a standard programming interface for SVGA displays, called the VESA BIOS Extension. Typically, an SVGA display can support a palette of up to 16,000,000 colors, although the amount of video memory in a particular computer may limit the actual number of displayed colors to something less than that. Image-resolution specifications vary. In general, the larger the diagonal screen measure of an SVGA monitor, the more pixels it can display horizontally and vertically. Small SVGA monitors (14-inch diagonal) usually display 800 pixels

horizontally by 600 pixels vertically. The largest monitors (20 inches or more diagonal measure) can display 1280 × 1024, or even 1600 × 1200, pixels.

distance

See “displacement”

distance education

Distance education is a formalized teaching system specifically designed to be carried out remotely. The students and the teacher are in different locations and lectures are transmitted through some type of technology such as closed-circuit or public television or an interactive Web site.

Distance education methods include:

- Voice-centered techniques, such as recordings, audioconferencing, and short-wave radio
- Video techniques, such as video cassettes, **videoconferencing**, or Web cameras
- Computer-centered techniques, such as computer-assisted instruction (CAI), which uses the computer as a teaching machine to present individual lessons, computer-mediated education (CME), which uses computer applications (e-mail, fax, or online chatting, for example) for delivery of instruction
- Print, such as books and hand-outs

Because distance education is less expensive to support and is not constrained by geographic considerations, it offers opportunities in situations where traditional education has difficulty operating. Students with scheduling or distance problems can benefit, as can workers, because distance education can be more flexible in terms of time and can be delivered virtually anywhere. Studies indicate that distance learning can be as effective as the traditional format when the methods are appropriate to the teaching tasks, there is student-teacher interaction, and the teachers provide students with appropriate and timely feedback.

distributed

Computing is said to be “distributed” when the computer programming and data that computers work on are spread out over more than one computer, usually over a network. Computing prior to low-cost computer power on the desktop, was organized in centralized “glass houses” (so-called because the computers were often shown to visitors through picture windows). Although these centers still exist, large and small enterprises over time are moving (distributing) applications and data to where they can operate most efficiently in the enterprise, to some mix of desktop workstations, local area network servers, regional servers, Web servers, and other servers. A popular trend has been **client/server** computing which is simply the view that a client computer can provide certain capabilities for a user

and request others from other computers that provide services for the clients. (The Web’s **Hypertext Transfer Protocol** protocol is an example of this idea.)

The Distributed Computing Environment (DCE) is a particular industry standard for implementing a distributed computing environment. Today, major software makers are fostering an object-oriented view of distributed computing. As a distributed publishing environment with **Java** and other products that help companies create distributed applications, the World Wide Web is accelerating the trend toward distributed computing and the view that, as Sun Microsystem’s slogan says, “The network is the computer.”

distributed authoring

See “WebDAV”

Distributed Component Object Model

See “DCOM”

Distributed Computing Environment

See “DCE”

distributed denial-of-service attack

On the Internet, a distributed denial-of-service (DDoS) attack is one in which a multitude of compromised systems attack a single target, thereby causing **denial of service** for users of the targeted system. The flood of incoming messages to the target system essentially forces it to shut down, thereby denying service to the system to legitimate users.

A **hacker** (or, if you prefer, **cracker**) begins a DDoS attack by exploiting a vulnerability in one computer system and making it the DDoS “master.” It is from the master system that the intruder identifies and communicates with other systems that can be compromised. The intruder loads cracking tools available on the Internet on multiple—sometimes thousands of—compromised systems. With a single command, the intruder instructs the controlled machines to launch one of many flood attacks against a specified target. The inundation of **packets** to the target causes a denial of service.

While the press tends to focus on the target of DDoS attacks as the victim, in reality there are many victims in a DDoS attack—the final target and as well the systems controlled by the intruder.

distributed file system

A distributed file system is a **client/server**-based **application** that allows **clients** to access and process data stored on the **server** as if it were on their own computer. When a user accesses a file on the server, the server sends the user a copy of the file, which is **cached** on the user’s computer while the data is being processed and is then returned to the server.

Ideally, a distributed file system organizes file and **directory** services of individual servers into a global directory in such a way that remote data access is not location-specific but is identical from any client. All files are accessible to all users of the global file system and organization is hierarchical and directory-based.

Since more than one client may access the same data simultaneously, the server must have a mechanism in place (such as maintaining information about the times of access) to organize updates so that the client always receives the most current version of data and that data conflicts do not arise. Distributed file systems typically use file or database replication (distributing copies of data on multiple servers) to protect against data access failures.

Sun Microsystems' Network File System (NFS), Novell NetWare, Microsoft's Distributed File System, and IBM/Transarc's DFS are some examples of distributed file systems.

Distributed interNet Applications Architecture

See "Web Solution Platform"

distributed learning

Distributed learning is a general term used to describe a multi-media method of instructional delivery that includes a mix of Web-based instruction, **streaming video** conferencing, face-to-face classroom time, distance learning through television or video, or other combinations of electronic and traditional educational models. Although distributed learning can be executed in a variety of ways, it is consistent in that it always accommodates a separation of geographical locations for part (or all) of the instruction, and focuses on learner-to-learner as well as instructor-to-learner interaction. Corporations and universities are using and promoting distributed learning for staff development, technical training, and advanced-degree coursework.

dithering

Dithering is the attempt by a computer program to approximate a color from a mixture of other colors when the required color is not available. For example, dithering occurs when a color is specified for a Web page that a **browser** on a particular **operating system** can't support. The browser will then attempt to replace the requested color with an approximation composed of two or more other colors it can produce. The result may or may not be acceptable to the graphic designer. It may also appear somewhat grainy since it's composed of different pixel intensities rather than a single intensity over the colored space.

Dithering also occurs when a display monitor attempts to display images specified with more colors than the monitor is equipped to handle.

Dithering is rather easy to confuse with **antialiasing**.

See "Direct Memory Access"

DMI

Desktop Management Interface (DMI) is an industry framework for managing and keeping track of hardware and software components in a system of personal computers from a central location. DMI was created by the Desktop Management Task Force (DMTF) to automate system management and is particularly beneficial in a network computing environment where dozens or more computers are managed. DMI is hardware and operating system-independent, independent of specific management **protocol**, easy for vendors to adopt, mappable to existing management protocols such as the Simple Network Management Protocol (**SNMP**), and used on network and non-network computers. DMI consists of four components:

- **Management Information Format (MIF):** An MIF is a text file that contains specific information about the hardware and software being used on a computer. An MIF file consists of one or more groups containing attributes, which describe each component. By default, each MIF file contains the standard component ID group. This group contains the product name, version, serial number, and the time and date of the last installation. The ID number is assigned based on when the component was installed in relation to other components. Manufacturers can create their own MIFs specific to a component. For example, a manufacturer might write an MIF file for a fax/modem that contains two groups: a fax group and a modem group. Some group attributes include warranty information, support phone numbers, and any errors encountered. This information is then sent to an MIF database.
- **Service layer:** The service layer is memory-resident code that acts as a mediator for the management interface and the component interface and allows management and component software to access MIF files in the MIF

database. The service layer is available as an operating system add-on and is a shared resource for all programs. Because the service layer must run all the time, it is designed not to use a lot of memory. The service layer also includes a common interface called the local agent, which is used to manage individual components.

- **Component interface (CI):** The CI is an **application program interface (API)** that sends status information to the appropriate MIF file via the service layer. Commands include the Get and Set command that modifies the MIF as needed and the Event command that notifies management software of critical events.
- **Management interface (MI):** The management software communicates with the service layer using the MI application program interface. The MI allows administrators to issue the Get and Set command and the List command that lists all the DMI-manageable devices.

To use DMI, you need a DMI-compliant management software package and a DMI-compliant computer. A DMI-compliant computer includes the CI, the MI, and the service layer. These drivers are available for download on the Internet.

Intel's **LANDesk Client Manager** is based on DMI.

DMZ

In computer networks, a DMZ (demilitarized zone) is a computer host or small network inserted as a "neutral zone" between a company's private network and the outside public network. It prevents outside users from getting direct access to a server that has company data. (The term comes from the geographic buffer zone that was set up between North Korea and South Korea following the war in the early 1950s.) A DMZ is an optional and more secure approach to a **firewall** and effectively acts as a **proxy server** as well.

In a typical DMZ configuration for a small company, a separate computer (or **host** in network terms) receives requests from users within the private network for access to Web sites or other companies accessible on the public network. The DMZ host then initiates sessions for these

requests on the public network. However, the DMZ host is not able to initiate a session back into the private network. It can only forward packets that have already been requested.

Users of the public network outside the company can access only the DMZ host. The DMZ may typically also have the company's Web pages so these could be served to the outside world. However, the DMZ provides access to no other company data. In the event that an outside user penetrated the DMZ host's security, the Web pages might be corrupted but no other company information would be exposed. Cisco, the leading maker of **routers**, is one company that sells products designed for setting up a DMZ.

See "domain name system"

docking station

A docking station is a hardware frame and set of electrical connection interfaces that enable a **notebook computer** to effectively serve as a **desktop computer**. The interfaces typically allow the notebook to communicate with a local printer, larger storage or backup drives, and possibly other devices that are not usually taken along with a notebook computer. A docking station can also include a network interface card (NIC) that attaches the notebook to a local area network (**LAN**).

Variations include the **port replicator**, an attachment on a notebook computer that expands the number of ports it can use, and the *expansion base*, which might hold a **CD-ROM** drive, a floppy disk drive, and additional storage.

DOCSIS

Now known as CableLabs Certified Cable Modems, DOCSIS (Data Over Cable Service Interface Specifications) is a **standard interface** for **cable modems**, the devices that handle incoming and outgoing data signals between a cable TV operator and a personal or business computer or television set. DOCSIS 1.0 was ratified by the International Telecommunication Union (**ITU-TS**) in March of 1998. Although "DOCSIS" continues to be used, the newer name emphasizes that the standard is now being used to certify the products of cable modem makers. Cable modems conforming to DOCSIS are now being marketed.

Cable operators whose existing customers have non-standard cable modems can handle them by adding backwards-compatible support to the DOCSIS **card** at the

cable operator's end. As DOCSIS continues to evolve to new versions, existing modems can be upgraded to the newer versions by changing the programming in the cable modem's **EEPROM memory**. DOCSIS-compliant cable modems are being integrated into **set-top boxes** for use with television sets. DOCSIS must also support or converge with the high definition television (**HDTV**) standard. The set-top box itself follows a standard known as OpenCable.

DOCSIS specifies **modulation** schemes and the **protocol** for exchanging bidirectional signals over cable. It supports downstream-to-the-user data rates up to 27 **Mbps** (megabits per second). Since this data rate is shared by a number of users and because many cable operators will be limited by a **T1** connection to the Internet, the actual downstream data rate to an individual business or home will be more like 1.5 to 3 Mbps. Since the upstream data flow has to support much smaller amounts of data from the user, it's designed for an aggregate data rate of 10 Mbps with individual data rates between 500 **Kbps** and 2.5 Mbps.

Cisco and Microsoft have endorsed DOCSIS. They are collaborating on a DOCSIS-compliant cable hybrid fiber-coax (**HFC**) system, called the Multimedia Cable Network System (**MCNS**), that will deliver services to residential, commercial, and educational customers.

document

1) In general, a document (noun) is a record or the capturing of some event or thing so that the information will not be lost. Usually, a document is written, but a document can also be made with pictures and sound. A document usually adheres to some convention based on similar or previous documents or specified requirements. Examples of documents are sales invoices, wills and deeds, newspaper issues, individual newspaper stories, oral history recordings, executive orders, and product specifications.

A document is a form of **information**. A document can be put into an electronic form and stored in a computer as one or more **files**. Often a single document becomes a single file. An entire document or individual parts may be treated as individual **data** items. As files or data, a document may be part of a **database**. Electronic Document Management (**EDM**) deals with the management of electronically-stored documents.

When using certain computer application programs such as a **word processor**, a document is the unit of saved work. Each document is saved as a uniquely named file.

In the computer industry, **documentation** is the information provided to a customer or other users about a product or the process of preparing it.

2) To document (verb) a fact, event, or other thing is to record or annotate it, meaning to put it into some relatively permanent form so that it can be retrieved later.

Document Object Model

Document Object Model (DOM), a programming interface specification being developed by the World Wide Web Consortium (**W3C**), lets a programmer create and modify **HTML** pages and **XML documents** as full-fledged program objects. Currently, HTML (Hypertext Markup Language) and XML (Extensible Markup Language) are ways to express a document in terms of a data structure. As program objects, such documents will be able to have their contents and data "hidden" within the object, helping to ensure control over who can manipulate the document. As objects, documents can carry with them the object-oriented procedures called **methods**. DOM is a strategic and open effort to specify how to provide programming control over documents. It was inspired in part by the advent of the new HTML capabilities generally called **dynamic HTML** and as a way to encourage consistent **browser** behavior with Web pages and their elements.

The Document Object Model offers two levels of interface implementation: DOM Core, which supports XML and is the base for the next level, and DOM HTML, which extends the model to HTML documents. Here are some highlights:

- Any HTML or XML element (with the possibility of a few exceptions) will be individually addressable by programming.
- The specification will be language-independent. The specification, when available, will be described using the interface definition language (**IDL**) from the industry open standard **CORBA**.
- In addition, the interface will be described in terms of the **Java** programming language and ECMAScript, an industry-standard **script** language based on **JavaScript** and **JScript**.
- DOM is not to be confused with Microsoft's **Component Object Model** (COM) or **Distributed Component Object Model** (DCOM). COM and DCOM are language-independent ways to specify objects and could be used to create DOM objects (documents) just as specific languages like Java could.

Progress of the Document Object Model specification can be followed at the W3C Web site.

Document Style Semantics and Specification Language

See "DSSSL"

document type definition

A document type definition (DTD) is a specific definition that follows the rules of the Standard Generalized Markup Language (**SGML**). A DTD is a specification that accompanies a document and identifies what the funny little codes (or markup) are that separate paragraphs, identify

topic headings, and so forth and how each is to be processed. By mailing a DTD with a document, any location that has a DTD "reader" (or "SGML compiler") will be able to process the document and display or print it as intended. This means that a single standard SGML compiler can serve many different kinds of documents that use a range of different markup codes and related meanings. The compiler looks at the DTD and then prints or displays the document accordingly.

documentation

In computer hardware and software product development, documentation is the information that describes the product to its users. It consists of the product technical manuals and online information (including online versions of the technical manuals and help facility descriptions). The term is also sometimes used to mean the *source* information about the product contained in design documents, detailed code comments, white papers, and blackboard session notes.

The term is derived from the idea that engineers and programmers "document" their products in formal writing. The earliest computer users were sometimes simply handed the engineers' or programmers' "documentation." As the product audience grew, it became necessary to add professional technical writers and editors to the process. Today, IBM and other companies look at developing product information based on what users actually need to do when using the product. In this task-oriented view, product information can be divided into and sometimes physically organized into these task categories: evaluating, planning for, setting up or installing, customizing, administering, using, and maintaining the product. Documentation is now often built directly into the product as part of the user interface and in help pages. Printed technical manuals are increasingly available at company Web sites in the form of Adobe Acrobat Portable Document Format (PDF) files or in HTML pages. IBM and Microsoft are among the world's largest publishers.

dogcow

The dogcow is a drawing of a rather indiscriminate-looking animal (it looks mostly like a dog but is said to have the spots of a cow) that is or has been used in the Apple **Macintosh** operating system to help tell users about their printing options. If you have the right level of Macintosh, you can see the dogcow by going to the Finder, looking under "Page Setup...", and then looking under printer options. The dogcow is used to show you what kind of option you've selected. For example, "Flip Horizontal" flips the dogcow to upside down.

If you click on the dogcow, Macintosh sends you the animal's characteristic cry of "Moof!" The dogcow icon was originally created by graphic artist Susan Kare. (She is also the artist who created the graphic interface for everyone's favorite Windows 3.1 card game, Solitaire.) Microsoft has

adopted its own version of the dogcow and uses it to demonstrate slide transitions in its PowerPoint application, although Apple retains its copyright on the original image and, believe it or not, the "Moof!"

OS X creators originally dropped the dogcow, but on-line petitions and press coverage designed to "bring back the dogcow" have made Apple executives aware of the tremendous cult following of this hybrid icon. (Legend has it that development teams at Apple still use the dogcow to identify a partly completed program that is unique and worth checking out.) It is expected that the dogcow will return in the next version of OS X.

dog-food

For hardware and software developers, dog-food is jargon for trying out a product on yourself before giving it to others or in order to develop a customer view of the product, as in "Let's eat our own dog-food." Keith Dawson, who conducts a "Jargon Watch" in his e-mail newsletter, reports that the term is also used as a verb. Developers at Microsoft are quoted as saying, "We have to dog-food this architecture before we release it." At Rational, a software development company, a developer is quoted as saying "We have to dog-food this puppy."

DOI

See "digital object identifier"

Dolby Digital

Dolby Digital, formerly known as AC-3, is a digital audio coding technique that reduces the amount of data needed to produce high quality sound. Dolby Digital takes advantage of how the human ear processes sound. When coding **noise** is close to the frequency of an audio signal, that audio signal masks the noise so that the human ear hears only the intended audio signal. Sometimes the coding noise is not in the same frequency of an audio signal and must be reduced or eliminated. By reducing, eliminating, or masking the noise, the amount of data is reduced to one tenth of the data on a compact disk (CD). Dolby Digital is used with digital versatile discs (DVDs), **high definition television** (HDTV), and digital cable and satellite transmissions. It has been selected as the audio standard for digital television (DTV). The European DVB standard does not use Dolby Digital for audio, but instead uses MPEG standard technology for both the audio and video signals.

Dolby Digital provides five full bandwidth channels, front left, front right, center, surround left, and surround right, for true surround sound quality. A low frequency effect (LFE) channel is included that provides the sound needed for special effects and action sequences in movies. The LFE channel is one-tenth of the bandwidth of the other channels and is sometimes erroneously called the subwoofer channel. This multichannel scheme is known as 5.1 channel.

Because not everyone has the equipment needed to take advantage of Dolby Digital's 5.1 channel sound, developers included a downmixing feature that ensures compatibility with any playback device. The decoder in the playback device delivers the audio signal specific to that particular device's ability. For example, a 5.1 channel audio signal is delivered to a mono television. The playback device's decoder downmixes the 5.1 channel signal to a mono signal allowing the television to use the received audio signal. Because the playback device does the downmixing, producers do not have to create multiple audio signals for each playback device.

The ATSC selected Dolby Digital as a standard for DTV because of its popularity with film producers and consumers, its ability to use a single audio **streaming video** because of the downmixing feature, and its high quality sound. The U.S. cable television industry has also adopted Dolby Digital for DTV applications. Most television facilities are not equipped to produce 5.1 channel sound. For this reason, many DTV programs use two-channel sound. The 5.1 channel sound is used primarily for theatrical films on pay-per-view channels and at theaters.

To take advantage of Dolby Digital 5.1 channel sound for satellite broadcasts, a satellite receiver that provides a Dolby Digital output is necessary. For cable users, all digital **set-top boxes** are equipped with a Dolby Digital two-channel decoder. To use 5.1 channel sound, a 5.1 channel-compliant set-top box is needed or an external 5.1 channel decoder unit. The proper sound equipment is also necessary.

DOLS

See "Domino Off-Line Services"

DOM

See "Document Object Model"

domain

Also see **domain name**.

In general, a domain is an area of control or a sphere of knowledge.

1) In computing and telecommunication in general, a domain is a sphere of knowledge identified by a name. Typically, the knowledge is a collection of facts about some program entities or a number of network points or addresses.

2) On the Internet, a domain consists of a set of network addresses. This domain is organized in levels. The top level identifies geographic or purpose commonality (for example, the nation that the domain covers or a category such as "commercial"). The second level identifies a unique place within the top level domain and is, in fact, equivalent to a unique address on the Internet (an **IP address**). Lower levels of domain may also be used.

Strictly speaking, in the Internet's domain name system (DNS), a domain is a name with which name server records are associated that describe subdomains or **hosts**. For example, "whatis.com" could be a domain with records for "www.whatis.com" and "www1.whatis.com," and so forth.

3) In Windows NT and Windows 2000, a domain is a set of network resources (applications, printers, and so forth) for a group of users. The user need only to log in to the domain to gain access to the resources, which may be located on a number of different servers in the network.

domain name

A **domain** name locates an organization or other entity on the Internet. For example, the domain name `www.totalbaseball.com`

locates an Internet address for "totalbaseball.com" at Internet point 199.0.0.2 and a particular host server named "www". The "com" part of the domain name reflects the purpose of the organization or entity (in this example, "commercial") and is called the **top-level domain** name. The "totalbaseball" part of the domain name defines the organization or entity and together with the top-level is called the **second-level domain** name. The second-level domain name maps to and can be thought of as the "readable" version of the Internet address.

A third level can be defined to identify a particular host server at the Internet address. In our example, "www" is the name of the server that handles Internet requests. (A second server might be called "www2".) A third level of domain name is not required. For example, the fully-qualified domain name could have been "totalbaseball.com" and the server assumed.

Subdomain levels can be used. For example, you could have "www.nyyankees.totalbaseball.com". Together, "www.totalbaseball.com" constitutes a *fully-qualified domain name*.

Second-level domain names must be unique on the Internet and registered with one of the ICANN-accredited registrars for the COM, NET, and ORG top-level domains. Where appropriate, a top-level domain name can be geographic. (Currently, most non-U.S. domain names use a top-level domain name based on the country the server is in.) To register a U.S. geographic domain name or a domain name under a country code, see an appropriate registrar.

On the Web, the domain name is that part of the Uniform Resource Locator (URL) that tells a domain name server using the domain name system (DNS) whether and where to forward a request for a Web page. The domain name is mapped to an IP address (which represents a physical point on the Internet).

More than one domain name can be mapped to the same Internet address. This allows multiple individuals, businesses, and organizations to have separate Internet identities while sharing the same Internet server.

J

K

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

To see the **IP address** for a domain name, use **ping**.

It may be worth noting that the domain name system contains an even higher level of domain than the top-level domain. The highest level is the *root domain*, which would be represented by a single dot (just as in many hierarchical file systems, a **root directory** is represented by a "/") if it were ever used. If the dot for the root domain were shown in the URL, it would be to the right of the top-level domain name. However, the dot is assumed to be there, but never shown.

domain name system

The domain name system (DNS) is the way that Internet **domain names** are located and translated into **Internet Protocol** addresses. A domain name is a meaningful and easy-to-remember "handle" for an Internet address.

Because maintaining a central list of domain name/IP address correspondences would be impractical, the lists of domain names and IP addresses are distributed throughout the Internet in a hierarchy of authority. There is probably a DNS server within close geographic proximity to your access provider that maps the domain names in your Internet requests or forwards them to other servers in the Internet.

Domino

Domino is the name of the applications and messaging **server** program for IBM's Lotus **Notes** product, a sophisticated **groupware application** that is being installed in many corporations. Notes lets a corporation and its workers develop communications- and **database**-oriented applications so that users at different geographic locations can share files with each other, comment on them publicly or privately (to groups with special access), keep track of development schedules, work projects, guidelines and procedures, plans, white papers, and many other documents, including multimedia files. IBM uses the Domino name to refer to a set of Notes server applications. Notes itself refers to the overall product.

The Notes and Domino servers interact with other Notes/Domino servers in a **distributed** network. As changes are made to a database at one server, updates are continually forwarded to replicated copies of these databases at the other servers so that users are always looking at the same information. In general, Notes follows the **client/server** model. The replication updates are made using Remote Procedure Call (**RPC**) requests. Notes can be coordinated with Web servers and applications on a company's **intranet**.

Domino Extensible Language

See "DXL"

Domino Off-Line Services

Domino Off-Line Services (DOLS) is an **add-on** toolkit, based on **Domino replication** and security features, that allows users to access and interact with Domino Web applications through a **browser** without requiring a network connection, and to synchronize changes to source data when they reconnect. Applications such as **e-mail** and **discussion groups** are fully functional. Work completed offline is synchronized when the user next connects to the network through a tool called the **iNotes Sync Manager**. DOLS decreases demands on network resources, and facilitates interactivity for a mobile workforce.

Using DOLS, a mobile worker could, for example, bring up a Web form in a Domino-based application and work with it, offline, in a meeting with a client. Changes specified could be sent out to **work group** members through the iNotes sync manager when the worker next connects to the network. The work group might meet, through a **teleconference**, to discuss the changes. Online, after the discussion, the mobile worker could replicate the discussion database, and later, offline, respond to questions. The changes to the discussion database would be synchronized again whenever the worker next had an opportunity to connect to the network.

dongle

A dongle (pronounced DONG-uhl) is a mechanism for ensuring that only authorized users can copy or use specific software **applications**, especially very expensive programs. Common mechanisms include a hardware key that plugs into a parallel or serial port on a computer and that a software application accesses for verification before continuing to run; special key diskettes accessed in a similar manner; and registration numbers that are loaded into some form of **ROM** (read-only memory) at the factory or during system setup.

If more than one application requires a dongle, multiple dongles can be daisy-chained together from the same port. Dongles are not in frequent use partly because enterprises don't like to have a serial or parallel port preempted for this use.

Doppler effect

The frequency and wavelength of an **electromagnetic field** are affected by relative motion. This is known as the *Doppler effect*. Only the radial (approaching or receding) component of motion produces this phenomenon. The Doppler effect also occurs with acoustic waves.

The Doppler effect is significant in low-earth-orbit (LEO) **satellite** systems. All LEO satellites are constantly moving relative to each other and to points on the surface. This causes variations in the frequencies and wavelengths of

received signals. In geostationary satellite systems, Doppler effect is not a factor unless the end user is on board a spacecraft or high-speed aircraft.

If the source of an EM field is approaching an observer, the **frequency** increases and the **wavelength** decreases. If the source is receding, the frequency decreases and the wavelength increases. If there are several observers, each moving radially at different speeds relative to the source of an EM field, every observer will perceive a unique frequency and wavelength for the EM field produced by the source.

A special type of **RADAR**, called *Doppler radar*, uses the Doppler effect to ascertain wind velocity in heavy thundershowers, tornadoes, and hurricanes. In a rotating storm such as a hurricane or tornado, the maximum sustained wind speed can be found by measuring the difference in frequency of echoes returned from approaching rain droplets and receding rain droplets. A more primitive form of Doppler radar is used by law enforcement personnel to enforce traffic speed limits.

DOS

DOS (Disk Operating System) was the first widely-installed **operating system** for personal computers. (Earlier, the same name had been used for an IBM operating system for a line of business computers.)

The first personal computer version of DOS, called **PC-DOS**, was developed for IBM by Bill Gates and his new Microsoft Corporation. He retained the rights to market a Microsoft version, called **MS-DOS**. PC-DOS and MS-DOS are almost identical and most users have referred to either of them as just "DOS." DOS was (and still is) a non-graphical line-oriented command- or menu-driven operating system, with a relatively simple interface but not overly "friendly" user interface. Its prompt to enter a command looks like this:
C:>

The first Microsoft Windows operating system was really an application that ran on top of the MS-DOS operating system. Today, Windows operating systems continue to support DOS (or a DOS-like user interface) for special purposes by emulating the operating system.

In the 1970s before the personal computer was invented, IBM had a different and unrelated DOS (Disk Operating System) that ran on smaller business computers. It was replaced by IBM's **VSE** operating system.

DOS Protected Mode Interface

DPMI (DOS Protected Mode Interface) is a program interface that allows an application program running under the Disk Operating System (DOS) to take advantage of a *DOS extender*, which lets the program address a larger range of random access memory (**RAM**) than the 640 kilobytes to which PC programs are basically constrained. To use the extender, the program must be in "protected mode," a mode

that ensures that program requests are not allowed to access certain portions of "protected" memory. (Programs running in the alternative "real mode" have access to all portions of memory, including system data.)

The first widely-distributed **operating system** for personal computers, DOS was designed to run on the Intel 8088 **microprocessor**. The 8088 provided a **megabyte** of RAM that could be addressed by a program instruction (that is, the total span of storage for storing and getting data back and forth between the microprocessor and RAM was a million bytes). Because certain space had to be reserved for "system" use (keeping track of applications, system status, and so forth), only 640 kilobytes was available for an application program. These bytes were contiguous in storage (that is, continuously adjacent to each other and not divided into different parts of RAM) and application programs were required to run and keep their data within this 640 kilobyte space. In fact, an instruction that violated the 640 kilobyte space would not be executed (thus protecting the system space in RAM). A program that ran in "real mode" could address the entire 1 megabyte of RAM including system data, but at the risk of writing data to the wrong place.

As new microprocessors such as the 80286 followed the 8088, DOS continued to preserve the 640 kilobyte addressing limitation so that newly-written application programs could continue to run on both the old as well as new microprocessors. The DOS extender program allowed application programs written for DOS to be freed from the 640K constraint by inserting memory management code into the application. Microsoft developed the DPMI for use on Windows 3.0 (which was itself a DOS application) and later gave the standard to an industry organization, the DPMI Committee.

Today's personal computers, using microprocessors that succeeded the 8088, typically contain 32 or more megabytes of RAM. Today's operating systems (including the latest DOS versions) come with extended memory management that frees the programmer from the original addressing constraints.

Besides the DPMI standard interface, two other standard extended memory management interfaces exist. Extended Memory Specification (XMS) is a program added to more recent versions of DOS and Windows when the system is loaded. It's called HIMEM.SYS. Another extended memory manager is the Virtual Control Program Interface (VCPI).

DOS/V and WIN/V

DOS/V is a version of **MS-DOS** that provides both English and Japanese language **command** interfaces and can be used for applications designed for either or both English and Japanese. DOS/V includes all the English-based commands and specific Japanese DOS/V commands. DOS/V gets its name because it requires a Video Graphics Array (**VGA**) display.

Before DOS/V, computers on the Japanese market were incompatible with machines made elsewhere and more expensive. Software developed for non-Japanese environments did not work on Japanese machines. In 1991, the Open Access Development Group (OADG), a consortium organized by IBM, developed DOS/V. Because DOS/V works on all IBM-compatible computers, foreign manufacturers were able to start selling their computers in the Japanese market. Competition brought prices down for computers, peripherals, and software. DOS/V also opened the door to Japanese versions of Windows 3.1, 95, and 98.

With the advent of Windows 3.1, a user was faced with new problems. A Windows user that needed Japanese capabilities had to juggle separate English and Japanese versions of Windows 3.1. This required installing Windows 3.1 twice in separate folders and rebooting when the other language version was needed. Installing separate English- and Japanese-based software applications was also necessary. WIN/V was developed to solve these problems.

WIN/V is an add-on to English versions of Windows 3.1 that emulates the Kanji-specific interface of Japanese versions of Windows 3.1, allowing users to use Japanese True Type fonts and Japanese applications without needing a Japanese version of Windows 3.1. WIN/V also allows users to use any printer that works with English versions of Windows 3.1. Since Windows 95 and 98 are truly multilingual, a WIN/V equivalent is no longer needed.

dot address

Tip: To find out the dot address (such as 205.245.172.72) for a given domain name, Windows users can go to their MS DOS prompt screen and enter: ping xxx.yyy where xxx is the second-level domain name like "whatis" and yyy is the top-level domain name like "com".

A dot address (sometimes known as a dotted quad address) refers to the notation that expresses the four-byte (32-bit) IP address as a sequence of four decimal numbers separated by dots. Each number represents the binary value of one of four bytes. Look at this Internet address, for example:

205.245.172.72

The first **byte** in the 32-bit sequence contains the binary equivalent of decimal 205, the second byte contains the equivalent of 245, the third of 172, and the fourth of 72.

The separation of the four numbers with dots makes the address easier to read. Of course, most of us remember an Internet location with a **domain name** rather than an Internet address. But we sometimes need the dot address form when we configure a Web browser or get set up with an access provider.

dot NET

See ".Net"

dot pitch

The dot pitch specification for a display monitor tells you how sharp the displayed image can be. The dot pitch is measured in millimeters (mm) and a smaller number means a sharper image. In desk top monitors, common dot pitches are .31mm, .28mm, .27mm, .26mm, and .25mm. Personal computer users will usually want a .28mm or finer. Some large monitors for presentation use may have a larger dot pitch (.48mm, for example). Think of the dot specified by the dot pitch as the smallest physical visual component on the display. A **pixel** is the smallest programmable visual element and maps to the dot if the display is set to its highest resolution. When set to lower resolutions, a pixel encompasses multiple dots.

Technically, in a cathode ray tube (CRT) display with a *shadow mask*, the dot pitch is the distance between the holes in the shadow mask, measured in millimeters (mm). The shadow mask is a metal screen filled with holes through which the three electron beams pass that focus to a single point on the tube's phosphor surface. In CRTs that use an *aperture grill* (a slotted form of mask), such as Sony's Trinitron flat-screen technology, the dot pitch is the difference between adjacent slots that pass through an electron beam of the same color.

dotcom

A dotcom is any **Web site** intended for business use and, in some usages, it's a term for any kind of Web site. The term is based on the **com** that forms the last part of the address for most commercial Web sites. The term is popular in news stories about how the business world is transforming itself to meet the opportunities and competitive challenges posed by the Internet and the World Wide Web. Beginning in mid-2000, as the stock market began to devalue many Internet stocks, the term became associated with a number of Web businesses that failed or suffered cutbacks.

Alternative spellings seen include: dot.com, dot-com, and dot com.

dots per inch

1) In computers, dots per inch (dpi) is a measure of the sharpness (that is, the density of illuminated points) on a display **screen**. The **dot pitch** determines the absolute limit of the possible dots per inch. However, the displayed **resolution of pixels** (picture elements) that is set up for the display is usually not as fine as the dot pitch. The dots per inch for a given picture resolution will differ based on the overall screen size since the same number of pixels are being spread out over a different space. Some users prefer the term "pixels per inch (**ppi**)" as a measure of display image sharpness, reserving dpi for use with the print medium.

2) In printing, dots per inch (dpi) is the usual measure of printed image quality on the paper. The average personal computer printer today provides 300 dpi or 600 dpi. Choosing the higher print quality usually reduces the speed of printing each page.

dotted quad

See “dot address”

double data rate synchronous dynamic random access memory

See “DDR SDRAM”

Double Density CD

See “Double-Density Compact Disc”

Double-Density Compact Disc

Double-Density Compact Disc (DDCD) is a CD format that increases the storage capacity of the disc through means such as increasing the number of tracks and pits (scores on the disc that are used to encode the data). Philips and Sony described the DDCD specifications in their 2000 document (known informally as the **Purple Book**).

Although DDCD did not receive much industry notice until Philips and Sony produced the Purple Book specifications, the Optical Disc Corporation (ODC) released a similar format, High Density CD (HDCD) in 1993, and Nimbus Technology and Engineering introduced their own Double-Density CD format in 1994. The general feeling in the industry is that DDCD has been introduced as a stop-gap measure to tide over the market until DVD inevitably solves its problems (such as standardization and compatibility issues) and makes the CD obsolete.

downlink and uplink

In **satellite** telecommunication, a downlink is the **link** from a satellite down to one or more ground stations or receivers, and an uplink is the link from a ground station up to a satellite. Some companies sell uplink and downlink services to television stations, corporations, and to other telecommunication carriers. A company can specialize in providing uplinks, downlinks, or both.

The following table shows the main **frequency** bands used for satellite links.

Frequency Band	Downlink	Uplink
C	3,700-4,200 MHz	5,925-6,425 MHz
Ku	11.7-12.2 GHz	14.0-14.5 GHz
Ka	17.7-21.2 GHz	27.5-31.0 GHz

The **C band** is the most frequently used. The Ka and Ku bands are reserved exclusively for satellite communication but are subject to rain attenuation. Some satellites carry transponders for both C and Ku bands.

downloading

Downloading is the transmission of a file from one computer system to another, usually smaller computer system. From the Internet user’s point-of-view, to download a file is to request it from another computer (or from a Web page on another computer) and to receive it.

Uploading is transmission in the other direction: from one, usually smaller computer to another computer. From an Internet user’s point-of-view, uploading is sending a file to a computer that is set up to receive it. People who share images with others on bulletin board systems (**BBS**) upload files to the BBS.

The **File Transfer Protocol** (FTP) is the Internet protocol for downloading and uploading files and a number of special applications can furnish FTP services for you. (However, if you are downloading through a Web page, the FTP request is set up for you by the Web page. You are usually asked where you want the downloaded file placed on your hard disk, and then the downloading transmission takes place.)

When you send an attached file with an e-mail note, this is just an attachment, not a download or an upload. In practice, many people use “download” and “upload” rather indiscriminately so you just have to understand the context. For example, if someone says to you “Download (or upload) such-and-such a file to me by e-mail,” they clearly mean “Send it to me as an attachment.”

In general, from the ordinary workstation or small computer user’s point-of-view, to download is to receive a file and to upload is to send a file.

downstream

1) In telecommunications generally, a transmission from an information **server** toward an **end user** is referred to as downstream and a transmission toward the server is referred to as upstream. In some transmission technologies, such as Digital Subscriber Line (**DSL**), the rates of data transfer upstream and downstream are not the same. In DSL, downstream data rates are higher since the kind of information that needs to get to the user (including still and video images and sound) requires a higher data rate. User responses back to the computer on the upstream path can be smaller since they are usually text-only.

2) In a **token ring**, a computer station is downstream from any station through which the token on the ring has already passed.

3) In **CATV**, a downstream **channel** is one used to transmit signals from the headend to the user. An upstream channel is one in another frequency band that is used to send signals from the user back to the headend.

DRAM

Dynamic random access memory (DRAM) is the most common kind of random access memory (**RAM**) for personal computers and workstations. **Memory** is the network of electrically-charged points in which a computer stores quickly accessible data in the form of 0s and 1s. *Random access* means that the PC processor can access any part of the memory or data storage space directly rather than having to proceed sequentially from some starting place. DRAM is dynamic in that, unlike static RAM (**SRAM**), it needs to have its storage cells refreshed or given a new electronic charge every few milliseconds. Static RAM does not need refreshing because it operates on the principle of moving current that is switched in one of two directions rather than a storage cell that holds a charge in place. Static RAM is generally used for **cache memory**, which can be accessed more quickly than DRAM.

DRAM stores each bit in a storage cell consisting of a capacitor and a transistor. Capacitors tend to lose their charge rather quickly; thus, the need for recharging. A variety of other RAM interfaces to the computer exist. These include: **EDO RAM** and **SDRAM**.

DRDRAM

RDRAM (Rambus Dynamic Random Access Memory) is a **memory** subsystem that promises to transfer up to 1.6 billion bytes per second. The subsystem consists of the random access memory (**RAM**), the RAM controller, and the **bus** (path) connecting RAM to the **microprocessor** and devices in the computer that use it. Direct Rambus (DRDRAM), a technology developed and licensed by the Rambus Corporation, is the latest version and is expected to help accelerate the growth of visually intensive interfaces such as **3-D**, interactive games, and streaming multimedia. Rambus is intended to replace the current main memory technology of dynamic random access memory (**DRAM**). Much faster data transfer rates from attached devices such as videocams using **FireWire** and the Accelerated Graphics Port (**AGP**) make it important to reduce the bottleneck in getting data

into the computer, staging it in RAM, and moving it through the microprocessor and to the display or other output devices.

Direct Rambus (DRDRAM) provides a two-byte (16 bit) bus rather than DRAM's 8-bit bus. At a RAM speed of 800 megahertz (800 million cycles per second), the peak data transfer rate is 1.6 billion bytes per second. Direct Rambus uses **pipelining** to move data from RAM to **cache** memory levels that are closer to the microprocessor or display. Up to eight operations may be underway at the same time. Rambus is designed to fit into existing **motherboard** standards. The components that are inserted into motherboard connections are called Rambus in-line memory modules (RIMMs). They can replace conventional **dual in-line memory module**.

An alternative to DRDRAM is SyncLink DRAM (**SDRAM**).

drilldown

As currently used in information technology, to drill down (verb) is to focus in on something. A drilldown (noun) is the act of focusing in.

The term is sometimes used when referring to moving down through a hierarchy of folders and files in a file system like that of Windows. It may also mean clicking through a series of dropdown menus in a graphical user interface.

Microsoft's Visual Studio Analyzer is said to "provide easy drilldown," possibly meaning that it allows the user to get quickly to a desired function or work unit.

The term *drillup* is also reported in the multi-dimensional data access query language (MDX), which contains the keywords DRILLDOWNMEMBER and DRILLUPMEMBER as well as TOGGLEDRILLSTATE.

driver

A driver is a program that interacts with a particular device or special (frequently optional) kind of software. The driver contains the special knowledge of the device or special software interface that programs using the driver do not. In personal computers, a driver is often packaged as a dynamic link library (**DLL**) file.

driver development kit

A driver development kit (DDK) is a set of programs and related files that are used to develop a new software or hardware **driver** or to update an existing **legacy application** driver for an **operating system**. (A driver is a relatively small program that addresses the unique requirements of a kind of hardware or a special software application.) Typically, DDKs are used by device manufacturers and software application developers. Some DDKs can be downloaded from the maker of the operating system. Others can be

purchased from a third party. A DDK typically includes sample drivers, **source code**, a **debugging** utility, a **compiler**, testing tools, other utilities, and documentation.

In addition to the kit, a driver developer needs to be familiar with the operating system or application the driver is for. Building a driver is typically a complicated process. Testing and debugging should be thorough so that the driver is released with as few errors as possible. There are several steps in building a driver:

- Writing the driver code. Common programming languages for writing drivers are **C** and **C++**.
- Testing and debugging the driver on a *checked build*. A checked build is an operating system and **kernel-mode** driver that has extra error checking and debugging information in the code to aid testing and debugging of the driver. Running with a checked build is slower and uses more memory. A checked build is done in a separate computer from the free build.
- Testing and debugging the driver on a *free build*. A free build or *retail build* is the **end user** version of the operating system built with full optimization and all debugging information removed. A free build is faster and uses less memory. It also shows driver problems that a user might encounter such as error messages or a computer freeze.
- Fine-tuning and performance checking of the driver on the free build.
- Additional testing and debugging as necessary, using both the checked and free builds of the driver.
- Final testing using the free build. A driver needs testing on a multiprocessor computer as well as on a single processor computer.

DRM

See “digital rights management”

dropout

A dropout is a small loss of data in an audio or video file on tape or disk. A dropout can sometimes go unnoticed by the user if the size of the dropout is small. Error correction schemes can compensate for the dropout by filling in data where a dropout is detected. With a larger section of missing data, the user will see or hear the error.

The reason for a dropout can be bad tape stock, a bad block on a hard disk, dirt, the age of the tape or disk, or something else. Older tapes, especially those dating to the analog era, are more susceptible to dropouts as they age. The magnetic particles on the tape become detached from the backing material, resulting in what is commonly known as shedding. Larger dropouts can be quite serious. On the master tape of a vintage recording, a dropout could be large enough to

render a selection unusable. In a video studio, a dropout on the SMPTE Time Code track could cause the machines slaving to the Time Code track to stop momentarily.

DSML

DSML (Directory Services Markup Language) is an application of the Extensible Markup Language (XML) that enables different computer network directory formats to be expressed in a common format and shared by different directory systems.

In the latest DSML specification, the related XML schema defines types of information found in today’s network and enterprise directories. It then defines a common XML document format that should be used to display the contents of each directory.

DSML has been heralded in industry press as a key component to the future of e-commerce and Web-based applications that link businesses and business processes together. Some examples of such business-to-business and business-to-customer applications include those in the area of supply chain management (SCM) or customer service, where someone in one company might use a Web interface to order items or to find out inventory levels on a vendor’s products. Information in a variety of directories may need to be furnished in order to display the correct information to an end user.

Bowstreet Software was the primary company behind the initial draft of the DSML specification. With the support of such early members as IBM, Microsoft, Novell, Oracle, and the Sun-Netscape Alliance, they founded the DSML Working Group, an organization committed to gaining acceptance for DSML among a variety of standards bodies, including: XML.org, the World Wide Web Consortium (W3C), and OASIS.

DSML is part of a handful of other efforts currently underway to adopt standards that make it easier for the contents of different directories to be shared across platforms and over the Internet. Other such efforts include the Directory Interoperability Forum (DIF) and the Directory Enabled Networking (DEN) initiative. Proponents of DSML indicate that DSML also works synergistically with LDAP directories, allowing LDAP directory information to be transmitted beyond the traditional firewall and into Internet-based applications.

DSN

DSP

See "digital signal processing"

DSS

See "Digital Signature Standard"

DSSSL

DSSSL (Document Style Semantics and Specification Language) is a standard for the processing of SGML (Standard Generalized Markup Language) documents. Whereas SGML is a standard for describing documents in terms of logical structure (rather than presentation), DSSSL describes how such a structured document might be presented visually, or converted to something else, or processed in some other way. SGML is a document structure language; DSSSL is a document processing language, especially for presentation or transformation.

A quick example: A Web page is an **HTML** (Hypertext Markup Language) document. HTML is a usage of SGML. Using DSSSL as a standard, someone could write a definition that would convert a Web page (HTML document) into a (let's call it) Tactile Markup Language (TML) document that could be processed by an online reader-and-sound converter for the blind. Or someone could write a definition that would transform the HTML document into a Microsoft Word document. DSSSL describes how you write such a definition, effectively how you map each markup tag from one definition (such as HTML) into some formatting process or markup tag in another "language."

DSSSL contains separate parts and you can choose which parts of the standard to use when creating a DSSSL definition. It contains standards for:

- A style language
- Flow objects
- A transformation language
- A document model
- A query language

The style language lets you describe how each document element (heading, paragraph, list, and so forth) will be formatted for displaying, printing, or other presentation in terms of such things as fonts, colors, and space measurements. Flow objects are the formatted objects themselves—for example, the paragraph described in terms of its typographic fonts. Flow objects are usually described as part of a style specification. The transformation language is a language for mapping a document in one SGML format to a document in another SGML format. The document model is a view of how any document is organized that uses a "grove, tree, branch, leaf..." metaphor. The query language lets you access parts of a document just as **SQL** lets you access particular data from a database.

Several DSSSL processors have been written that are available for downloading from the Web.

DSTP

DSTP (Data Space Transfer Protocol) is a **protocol** that is used to index and retrieve data from a number of **databases**, **files**, and other data structures using a key that can find all the related data about a particular object across all of the data. The data is typically **distributed** among a number of **servers** in a network. The servers, called DSTP servers, understand how to index and retrieve appropriate data, using the key, which is called a Universal Correlation Key (UCK). DSTP can be considered a tool for **data mining**.

DSTP is similar in concept to the **NNTP**, which allows Internet users to access the online discussions known as Usenet newsgroups.

DSTP makes use of the Extensible Markup Language (**XML**). For an existing database, an XML file is created in which a UCK key or tag describes corresponding database columns.

DTD

See "document type definition"

DTE

In computer data transmission, DTE (Data Terminal Equipment) is the **RS-232C** interface that a computer uses to exchange data with a modem or other serial device. For further information about the DTE interface and its relationship to the Data Communication Equipment (DCE) interface, see **RS-232C**.

dual boot

A dual boot system is a computer system in which two **operating systems** are installed on the same hard drive, allowing either operating system to be loaded and given control. When you turn the computer on, a **boot** manager program displays a menu, allowing you to choose the operating system you wish to use. A boot manager works by replacing the original Master Boot Record (**MBR**) with its own so that the boot manager program loads instead of an operating system. Some popular boot manager programs are LILO, System Commander, and Partition Magic. Common combinations of operating systems used on dual boot systems include **Linux** and **Windows NT** and Windows 98 with one install of Windows being in a different language, such as Spanish. Since more than two operating systems can be installed on a computer, the term *multiboot system* is sometimes used.

dual in-line memory module

See “DIMM”

dual tone multi frequency

See “DTMF”

Dublin Core

Dublin Core is an initiative to create a digital “library card catalog” for the Web. Dublin Core is made up of 15 **metadata** (data that describes data) elements that offer expanded cataloging information and improved document indexing for **search engine** programs.

The 15 metadata elements used by Dublin Core are: title (the name given the resource), creator (the person or organization responsible for the content), subject (the topic covered), description (a textual outline of the content), publisher (those responsible for making the resource available), contributor (those who added to the content), date (when the resource was made available), type (a category for the content), format (how the resource is presented), identifier (numerical identifier for the content such as a URL), source (where the content originally derived from), language (in what language the content is written), relation (how the content relates to other resources, for instance, if it is a chapter in a book), coverage (where the resource is physically located), and rights (a link to a copyright notice).

Two forms of Dublin Core exist: Simple Dublin Core and Qualified Dublin Core. Simple Dublin Core expresses elements as attribute-value pairs using just the 15 metadata elements from the Dublin Core Metadata Element Set. Qualified Dublin Core increases the specificity of metadata by adding information about encoding schemes, enumerated

lists of values, or other processing clues. While enabling searches to be more specific, qualifiers are also more complex and can pose challenges to interoperability.

Each method of recording or transferring Dublin Core metadata has its plusses and minuses. **HTML**, **XML**, **RDF**, and relational databases are among the more common methods.

The Dublin Core Metadata Initiative began in 1995, taking its name from the location of the original workshop, Dublin, Ohio. It has since become international in scope and has representatives from more than 20 countries now contributing. Dublin Core has always held that resource discovery should be independent from the medium of the resource. So, while Dublin Core targets electronic resources, it aims to be flexible enough to help in searches for more traditional formats of data too. Web sites, though, are the most common users of Dublin Core.

duh

In general, duh (pronounced DUH, prolonging the UH, pitching the voice a bit low, and inflecting it with an intonation of imbecility or sarcasm or both, depending on the usage, is a colloquial comment on one’s (or someone else’s) lack of knowledge or brain power.

Here are some usages:

- 1) It can be used as an epithet when confounded by new technology. For example, someone unfamiliar with computers looking at a **Windows 2000 desktop** for the first time, might say “Duh” out loud and to no one in particular. In this usage, duh expresses the state of what is, in the late 20th century vernacular, “being totally clueless.”
- 2) A common use of duh is to confess an error.
- 3) Another common use is to suggest to someone that you are telling them something obvious, but you’re telling them anyway because you don’t expect that they are all that alert mentally.

duplex

In telecommunication, duplex communication means that both ends of the communication can send and receive **signals** at the same time. **Full-duplex** communication is the same thing. **Half-duplex** is also bidirectional communication but signals can only flow in one direction at a time. Simplex communication means that communication can only flow in one direction and never flow back the other way.

An ordinary telephone conversation is a duplex communication. Most inexpensive speakerphones in conference rooms are half-duplex communication. (If you’re speaking, you can’t hear anyone else interrupt. You have to pause to let others speak.)

duty cycle

Duty cycle is the proportion of time during which a component, device, or system is operated. The duty cycle can be expressed as a ratio or as a percentage. Suppose a disk drive operates for 1 second, then is shut off for 99 seconds, then is run for 1 second again, and so on. The drive runs for one out of 100 seconds, or 1/100 of the time, and its duty cycle is therefore 1/100, or 1 percent.

The more a circuit, machine or component is used, the sooner it will wear out. Therefore, the higher the duty cycle, the shorter the useful life, all other things being equal. If the above-mentioned disk drive has a life expectancy of 1,000,000 hours based on a 1 percent duty cycle, that same device's expectancy would probably be about 500,000 hours based on a duty cycle of 2 percent, and 2,000,000 hours based on a duty cycle of 0.5 percent.

DVB

See "Digital Video Broadcasting"

DVD

See "digital versatile disc"

DVD Forum

The DVD Forum is an international organization made up of companies using or manufacturing digital versatile disc (DVD)-related products. The Forum, which was originally called the DVD Consortium, was created in 1995 when ten companies (Hitachi, Matsushita, Mitsubishi, Philips, Pioneer, Sony, Thomson Multimedia, Time Warner, Toshiba Corporation, and Victor) joined for the common purpose of promoting DVD worldwide and establishing standardized formats of each DVD application for the marketplace.

From ten founding members, the DVD Forum membership has grown to include some 230 companies worldwide. The Forum's activities are directed by a steering committee that is elected every second year. Separate working groups are established to define specifications, which currently include **DVD-Video** (this is the most familiar format), **DVD-Read-Only Memory (DVD-ROM)**, **DVD-Recordable (DVD-R)**, **DVD-Rewritable (DVD-RW)**, and **DVD-Audio (DVD-A)**. The DVD Forum issues specifications as separate books of the DVD specification, identified by letters (for example, DVD-R is laid out in Book D). A Verification Task Force (VTF) exists to define test specifications, tools, and procedures to be used and to ensure that products bearing the official DVD logo comply with all specifications.

DVD-A

See "DVD-Audio"

DVD-Audio

DVD-Audio (DVD-A) is a Digital Versatile Disc (**DVD**) format, developed by Panasonic, that is specifically designed to hold **audio** data, and particularly, high-quality music. The DVD Forum, consisting of 230 leading companies worldwide, released the final DVD-A specification in March of 1999. The new DVD format is said to provide at least twice the sound quality of audio CD on discs that can contain up to seven times as much information. Various types of DVD-A-compatible DVD players are being manufactured, in addition to the DVD-A players specifically developed for the format.

Almost all of the space on a DVD video disc is devoted to containing video data. As a consequence, the space allotted to audio data, such as a **Dolby Digital** 5.1 soundtrack, is severely limited. A **lossy compression** technique—so-called because some of the data is lost—is used to enable audio information to be stored in the available space, both on standard CDs and **DVD-Video** discs. In addition to using lossless compression methods, DVD-A also provides more complexity of sound by increasing the **sampling rate** and the frequency range beyond what is possible for the space limitations of CDs and DVD-Video. DVD-Audio is 24-bit, with a sampling rate of 96 kHz; in comparison, DVD-Video soundtrack is 16-bit, with a sampling rate of 48 kHz, and standard audio CD is 16-bit, with a sampling rate of 44.1 kHz.

Although DVD-A is designed for music, it can also contain other data, so that—similarly to **Enhanced CD**—it can provide the listener with extra information, such as liner notes and images. A variation on the format, **DVD-AudioV**, is designed to hold a limited amount of conventional DVD video data in addition to DVD-Audio. DVD-A is backed by most of the industry as the technology that will replace the standard audio CD. The major exceptions are Philips and Sony, whose Super Audio CD (**SACD**) provides similar audio quality. Like DVD-A, SACD offers 5.1 channel surround sound in addition to 2-channel stereo. Both formats improve the complexity of sound by increasing bit rates and sampling frequencies, and can be played on existing CD players, although only at quality levels similar to those of traditional CDs.

DVD-AudioV

See "DVD-Audio"

DWDM

See "dense wavelength division multiplexing"

DXL

DXL (Domino Extensible Language) is a specific version of Extensible Markup Language (XML) for Lotus Domino data. **Domino** is a server program for Lotus **Notes**, a **groupware** application that is used by many businesses.

The Document Type Definition (DTD) for DXL defines the **markup tags** needed for working with XML within the Domino environment. This provides a consistent data format for non-Domino-equipped businesses when they access Domino data. Future versions of DXL will support Domino design elements, so non-Domino-equipped organizations can create or modify Domino documents.

DXL data must be converted to conventional XML when used outside the Domino environment. Conversely, XML data must be converted to DXL before it can be used in the Domino environment. Conversions in either direction are done by an Extensible Stylesheet Language Transformation (XSLT) processor.

dynamic and static

In general, *dynamic* means *energetic, capable of action and/or change, or forceful*, while *static* means *stationary or fixed*. In computer terminology, *dynamic* usually means *capable of action and/or change*, while *static* means *fixed*. Both terms can be applied to a number of different types of things, such as programming languages (or components of programming languages), Web pages, and application programs.

When a Web page is requested (by a computer user clicking a hyperlink or entering a **URL**), the **server** where the page is stored returns the **HTML** document to the user's computer and the **browser** displays it. On a static Web page, this is all that happens. The user may interact with the document through clicking available links, or a small program (an **applet**) may be activated, but the document has no capacity to return information that is not pre-formatted. On a dynamic Web page, the user can make requests (often through a **form**) for data contained in a **database** on the server that will be assembled **on the fly** according to what is requested. For example the user might want to find out information about a theatrical performance, such as theater locations and ticket availability for particular dates. When the user selects these options, the request is relayed to the server using an intermediary, such as an Active Server Page (**ASP**) **script** embedded in the page's HTML. The intermediary tells the server what information to return. Such a Web page is said to be dynamic.

A set of HTML capabilities are provided that help a designer create dynamic Web pages. This set of capabilities is generally known as **dynamic HTML**.

There are dynamic and static programming languages. In a dynamic language, such as **Perl** or **LISP**, a developer can create **variables** without specifying their type. This creates more flexible programs and can simplify **prototyping** and

some **object-oriented** coding. In a static programming language, such as **C** or **Pascal**, a developer must declare the type of each variable before the code is compiled, making the coding less flexible, but also less error-prone.

Dynamic Data Exchange

In the Windows, OS/2, and (with third-party development kits) other operating systems, Dynamic Data Exchange (DDE) allows information to be shared or communicated between programs. For example, when you change a form in your database program or a data item in a spreadsheet program, they can be set up to also change these forms or items anywhere they occur in other programs you may use. DDE is interprocess communication (**IPC**) that uses shared memory as a common exchange area and provides applications with a protocol or set of commands and message formats. DDE uses a client/server model in which the application requesting data is considered the client and the application providing data is considered the server.

Thousands of applications use DDE, including Microsoft's Excel, Word, Lotus 1-2-3, AmiPro, Quattro Pro, and Visual Basic.

Another facility, NetDDE, allows programs to converse across networks. For example, a Superbase program on one network node could be updated whenever an Excel program in network node was updated. Both nodes must have NetDDE installed.

dynamic DNS service

A dynamic DNS (domain name system) service is a company that charges a small fee to allow a user connecting to the Internet with a **dynamic IP address** to be able to use applications that require a **static IP address**.

Using a dynamic DNS service works as if there was an old-fashioned telephone message service at your computer's disposal. When a user registers with a DNS service and connects to the Internet with a dynamic IP address, the user's computer contacts the DNS service and lets them know what dynamic IP address it has been assigned from the pool; the service works with the DNS server to forward the correct address to the requesting computer. (Think of calling the message service and saying "Hi. I can be reached at 435.44.32.111 right now. Please tell anyone who tries to reach me to call that number.") Using a dynamic DNS service to arrange for computers to find you even though you are using a dynamic IP address is the next-best thing to having a static IP.

dynamic fonts

Dynamic fonts are a feature of Netscape's Communicator suite of products that enables a Web page designer to specify or create a special font style for a Web page or site. A **font** file (which describes how to display a particular set of font

images) is downloaded as a **plug-in** from the Web server along with the first page that uses it. Netscape's viewing support uses TrueDoc Technology from Bitstream.

Dynamic Host Configuration Protocol

Dynamic Host Configuration Protocol (DHCP) is a communications **protocol** that lets network administrators manage centrally and automate the assignment of Internet Protocol (IP) addresses in an organization's network. Using the Internet Protocol, each machine that can connect to the Internet needs a unique **IP address**. When an organization sets up its computer users with a connection to the Internet, an IP address must be assigned to each machine. Without DHCP, the IP address must be entered manually at each computer and, if computers move to another location in another part of the network, a new IP address must be entered. DHCP lets a network administrator supervise and distribute IP addresses from a central point and automatically sends a new IP address when a computer is plugged into a different place in the network.

DHCP uses the concept of a "lease" or amount of time that a given IP address will be valid for a computer. The lease time can vary depending on how long a user is likely to require the Internet connection at a particular location. It's especially useful in education and other environments where users change frequently. Using very short leases, DHCP can dynamically reconfigure networks in which there are more computers than there are available IP addresses.

DHCP supports static addresses for computers containing Web servers that need a permanent IP address.

DHCP is an alternative to another network IP management protocol, Bootstrap Protocol (**BOOTP**). DHCP is a more advanced protocol, but both configuration management protocols are commonly used. Some organizations use both protocols, but understanding how and when to use them in the same organization is important. Some operating systems, including Windows NT/2000, come with DHCP servers. A DHCP or BOOTP client is a program that is located in (and perhaps downloaded to) each computer so that it can be configured.

dynamic HTML

Dynamic HTML is a collective term for a combination of new Hypertext Markup Language (**HTML**) tags and options, that will let you create Web pages more animated and more responsive to user interaction than previous versions of HTML. Much of dynamic HTML is specified in HTML 4.0. Simple examples of dynamic HTML pages would include (1) having the color of a text heading change when a user passes a mouse over it or (2) allowing a user to "drag and drop" an image to another place on a Web page. Dynamic HTML can allow Web documents to look and act like desktop applications or multimedia productions.

The features that constitute dynamic HTML are included in recent versions of the Netscape, Internet Explorer, and other web browsers. While HTML 4.0 is supported by both Netscape and Microsoft browsers, some additional capabilities are supported by only one of the browsers. The biggest obstacle to the use of dynamic HTML is that, since many users are still using older browsers, a Web site must create two versions of each site and serve the pages appropriate to each user's browser version. The concepts and features in Dynamic HTML that both Netscape and Microsoft support are:

- An object-oriented view of a Web page and its elements
- Cascading style sheets and the layering of content
- Programming that can address all or most page elements
- Dynamic fonts

An Object-Oriented View of Page Elements

Each page element (division or section, heading, paragraph, image, list, and so forth) is viewed as an "object." (Microsoft calls this the "Dynamic HTML Object Model." Netscape calls it the "HTML Object Model." W3C calls it the "Document Object Model.") For example, each heading on a page can be named, given attributes of text style and color, and addressed by name in a small program or "script" included on the page. This heading or any other element on the page can be changed as the result of a specified event such a mouse passing over or being clicked or a time elapsing. Or an image can be moved from one place to another by "dragging and dropping" the image object with the mouse. (These event possibilities can be viewed as the reaction capabilities of the element or object.) Any change takes place immediately (since all variations of all elements or objects have been sent as part of the same page from the Web server that sent the page). Thus, variations can be thought of as different properties of the object.

Not only can element variations change text wording or color, but everything contained within a heading object can be replaced with new content that includes different or additional HTML as well as different text. Microsoft calls this the "Text Range technology."

Style Sheets and Layering

A **style sheet** describes the default style characteristics (including the page layout and font type style and size for text elements such as headings and body text) of a document or a portion of a document. For Web pages, a style sheet also describes the default background color or image, hypertext link colors, and possibly the content of page. Style sheets help ensure consistency across all or a group of pages in a document or a Web site.

Dynamic HTML includes the capability to specify style sheets in a "**cascading style sheet**" fashion (that is, linking to or specifying different style sheets or style statements with predefined levels of precedence within the same or a set of

related pages). As the result of user interaction, a new style sheet can be made applicable and result in a change of appearance of the Web page. You can have multiple layers of style sheet within a page, a style sheet within a style sheet within a style sheet. A new style sheet may only vary one element from the style sheet above it.

Layering is the use of alternate style sheets or other approaches to vary the content of a page by providing content layers that can overlay (and replace or superimpose on) existing content sections. Layers can be programmed to appear as part of a timed presentation or as the result of user interaction. In Internet Explorer, Microsoft implements layers through style sheets. Netscape supports the style sheet approach but also offers a new HTML ... tag set (that Microsoft does not support). Both approaches are being considered by the W3C Working Committee and both companies say they will support whatever W3C decides will be the recommended approach.

Programming

Although **JavaScript**, **Java applet**, and **ActiveX** controls were present in previous levels of Web pages, dynamic HTML implies an increased amount of programming in Web pages since more elements of a page can be addressed by a program.

Dynamic Fonts

Netscape includes **dynamic fonts** as part of dynamic HTML. This feature of Netscape's Navigator browser in its Communicator suite lets Web page designers include font files containing specific font styles, sizes, and colors as part of a Web page and to have the fonts downloaded with the page. That is, the font choice no longer is dependent on what the browser provides.

dynamic link library

In computers, a dynamic link library (DLL) is a collection of small programs, any of which can be called when needed by a larger program that is running in the computer. The small program that lets the larger program communicate with a specific device such as a printer or scanner is often packaged as a DLL program (usually referred to as a DLL file). DLL files that support specific device operation are known as **device drivers**.

The advantage of DLL files is that, because they don't get loaded into random access memory (**RAM**) together with the main program, space is saved in RAM. When and if a DLL file is needed, then it is loaded and run. For example, as long as a user of Microsoft Word is editing a document, the printer DLL file does not need to be loaded into RAM. If the user decides to print the document, then the Word application causes the printer DLL file to be loaded and run.

A DLL file is often given a ".dll" file name suffix. DLL files are dynamically linked with the program that uses them during program execution rather than being **compiler** with the main program. The set of such files (or the DLL) is somewhat comparable to the library routines provided with programming languages such as C and C++.

dynamic multi-pathing

Dynamic multi-pathing (DMP) is a type of communication **path control** software application. Path control is an approach to optimizing configuration and routing management for storage networks; DMP is used to automate these processes for storage network data backup and restoration. DMP was designed in response to the complex needs of storage networks as compared to ordinary data networks: Connection failures in data networks generally just mean that the connection must be retried; in storage networks, however, a failure is more likely to cause a system **crash**. The margin for error is smaller for storage networks as well: Whereas error recovery within minutes is acceptable for properly functioning data networks, for storage networks it should be within seconds—and preferably milliseconds.

To address these differences, storage networks should be designed to enable the greatest possible configuration flexibility and system availability. However, added flexibility also increases the possibility of connection failures: Where a storage system at one time might have consisted of a single storage device connected to a single **host** by a single cable, a storage system today typically consists of multiple diverse devices in an interconnected network **topology**. DMP software applications automatically reroute data through alternate paths in the event of a connection failure.

dynamic packet filter

A dynamic packet filter is a **firewall** facility that can monitor the state of active connections and use this information to determine which network **packets** to allow through the firewall. By recording session information such as **IP addresses** and **port** numbers, a dynamic packet filter can implement a much tighter security posture than a static packet filter.

For example, assume that you wish to configure your firewall so that all users in your company are allowed out to the Internet, but only replies to users' data requests are let back in. With a static packet filter, you would need to permanently allow in replies from all external addresses, assuming that users were free to visit any site on the Internet. This kind of filter would allow an attacker to sneak information past the filter by making the packet look like a reply (which can be done by indicating "reply" in the packet header).

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

By tracking and matching requests and replies, a dynamic packet filter can screen for replies that don't match a request. When a request is recorded, the dynamic packet filter opens up a small inbound hole so only the expected data reply is let back through. Once the reply is received, the hole is closed. This dramatically increases the security capabilities of the firewall.

dynamic port numbers

The dynamic port numbers (also known as the *private port numbers*) are the **port numbers** that are available for use by any application to use in communicating with any other application, using the Internet's Transmission Control Protocol (**TCP**) or the User Datagram Protocol (**UDP**). When one application communicates with another application at another **host** computer on the Internet, it specifies that application in each data transmission by using its port number. The port numbers range from 0 through 65535. However, certain port numbers—the **well-known port numbers** and the **registered port numbers**—are registered and administered by the Internet Corporation for Assigned Names and Numbers (**ICANN**) for use by certain classes of applications. The dynamic port numbers are in the highest range, from 49152 through 65535.

Before the arrival of ICANN, the port numbers were administered by the Internet Internet Assigned Numbers Authority (**IANA**).

dynamic random access memory

See "DRAM"

dynamic range

Dynamic range describes the ratio of the softest sound to the loudest sound in a musical instrument or piece of electronic equipment. This ratio is measured in **decibels** (abbreviated as dB) units.

Dynamic range measurements are used in **audio** equipment to indicate a component's maximum output signal and to rate a system's noise floor. As a reference point, the dynamic range of human hearing, the difference between the softest sound we can perceive and the loudest, is about 120 dB.

Compressors, expanders, and noise gates are processing devices that are used in audio to alter the dynamic range of a given signal. This is done to achieve a more consistent sound when recording or as a special effect (by radically altering the dynamics of a sound, thereby creating a sound not possible from the original source).

E

E Ink

E Ink is an electronic device that is similar to a computer display, but with qualities that enable it to be used for applications such as **eBooks**, **electronic newspapers**, portable signs, and foldable, rollable displays. E Ink Corp. (a Cambridge, Massachusetts company) and Lucent are developing the device, which combines E Ink's **electronic ink** with Lucent's **flexible transistors**. Prototypes have featured 25-inch display areas involving several hundred **pixels**. Although the new technology's more complex applications—such as electronic newspapers and improved e-books that are very similar to traditional books—are likely still at least 10 years in the future, E Ink is currently being tried for simpler applications, such as retail signage.

The E Ink prototypes combine thin, plastic transistors with **polymer LEDs** (**light-emitting diodes**) to create what are called **smart pixels**. The process involved—which is not dissimilar to traditional printing processes—uses silicon rubber stamps to actually print tiny computer circuits onto the surface. The electronic ink used is a liquid substance consisting of millions of tiny capsules floating in a substance like vegetable oil. The capsules, which are filled with a dark dye, contain negatively charged white chips that move either up or down within the capsules in response to a positive charge applied to the medium's surface. Information to be displayed is downloaded through a connection to a computer or a cell phone, or created with mechanical tools such as an electronic "pencil," and remains fixed until another charge is applied to change it. The devices use very low power: according to a spokesperson, prototypes of the device have been running on watch batteries.

Xerox, in partnership with 3M is working on a competing technology, called **Gyricon**.

e-

1) e- or E- (sometimes without the hyphen) is a prefix that has spread from **e-mail** to other forms of human enterprise as they emerge on the **Internet**. Well-known examples are **e-commerce**, **e-business**, **e-tailing**, and **ezine**. The e is a shortening of "electronic" and e-mail is still sometimes referred to as electronic mail. The sense of "electronic" in this usage generally had and has to do with telecommunications. Whatever it was you used to do before, now you can do it (send or receive it or have a transaction with others) electronically over a telecommunications line.

If the e- prefix denotes telecommunication, the *cyber* prefix denotes computing, although this often implicitly suggests network computing and telecommunication as well (as in **cyberspace**). The lower-case *i* (for Internet) prefix, which is

usually without the hyphen, has also gained currency as a prefix for a name that instantly associates it with the Internet.

2) At least one user reports colloquial usage of the e alone as a verb, especially as a short form for "to email." For example: "I'll e it to you later, baby."

E1, E2, E3...

See "E-carrier system"

E2E

On the Internet, E2E has been used to mean exchange-to-exchange—that is, the exchange of information or transactions between Web sites that themselves serve as exchanges or brokers for goods and services between businesses. E2E can be thought of as a form of **B2B**.

E2K

E2K stands for the Exchange 2000 **messaging** and collaboration server product from Microsoft.

e3000

See "HP e3000"

EAI

EAI (enterprise application integration) is a business computing term for the plans, methods, and tools aimed at modernizing, consolidating, and coordinating the computer **applications** in an **enterprise**. Typically, an enterprise has existing **legacy applications** and **databases** and wants to continue to use them while adding or migrating to a new set of applications that exploit the Internet, **e-commerce**, **extranet**, and other new technologies. EAI may involve developing a new total view of an enterprise's business and its applications, seeing how existing applications fit into the new view, and then devising ways to efficiently reuse what already exists while adding new applications and data.

EAI encompasses methodologies such as **object-oriented programming**, distributed, cross-platform program communication using message brokers with **Common Object Request Broker Architecture** and **COM+**, the modification of enterprise resource planning (**ERP**) to fit new objectives, enterprise-wide content and data distribution using common databases and data standards implemented with the Extensible Markup Language (**XML**), **middleware**, message queueing, and other approaches.

C

D

EBCDIC

EBCDIC (pronounced either "ehb-suh-dik" or "ehb-kuh-dik") is a **binary** code for alphabetic and numeric characters that IBM developed for its larger operating systems. It is the code for text files that is used in IBM's OS/390 operating system for its S/390 servers and that thousands of corporations use for their **legacy applications** and **databases**. In an EBCDIC file, each alphabetic or numeric character is represented with an 8-bit binary number (a string of eight 0's or 1's). 256 possible characters (letters of the alphabet, numerals, and special characters) are defined.

IBM's PC and workstation operating systems do not use IBM's proprietary EBCDIC. Instead, they use the industry standard code for text, **ASCII**. Conversion programs allow different operating systems to change a file from one code to another.

Also see **Unicode**.

M

eBook

An eBook is an *electronic* version of a traditional print book that can be read by using a personal computer or by using an eBook reader. (An eBook reader can be a software application for use on a computer, such as Microsoft's free *Reader* application, or a book-sized computer that is used solely as a reading device, such as Nuvomedia's **Rocket eBook**.) Users can purchase an eBook on diskette or CD, but the most popular method of getting an eBook is to purchase a downloadable file of the eBook (or other reading material) from a Web site (such as Barnes and Noble) to be read from the user's computer or reading device. Generally, an eBook can be downloaded in five minutes or less.

Although it is not necessary to use a reader application or device in order to read an eBook (most books can be read as **PDF** files), they are popular because they enable options similar to those of a paper book—readers can bookmark pages, make notes, highlight passages, and save selected text. In addition to these familiar possibilities, eBook readers also include built-in dictionaries, and alterable font sizes and styles. Typically, an eBook reader hand-held device weighs from about twenty-two ounces to three or four pounds and

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

can store from four thousand to over half a million pages of text and graphics. A popular feature is its back-lit screen (which makes reading in the dark possible).

Some eBooks can be downloaded for free or at reduced cost, however, prices for many eBooks—especially bestsellers—are similar to those of hardcover books, and are sometimes higher. Most eBooks at Barnes and Noble, for example, are comparable in price to their traditional print versions.

EBPP

On the Internet, electronic bill presentment and payment (EBPP) is a process that enables bills to be created, delivered, and paid over the Internet. The service has applications for many industries, from financial service providers to telecommunications companies and utilities.

Although buying products over the Internet with a credit card has become a common occurrence, viewing the credit card bill itself—and making payments to settle the bill electronically—has not. This is expected to dramatically change as new EBPP products are introduced that include features such as secure e-mail delivery, and also as EBPP technology becomes more common in business-to-business e-commerce.

One of the obstacles to widespread adoption of EBPP lies in the complexity of billing systems and processes used by competing banks and financial institutions. Some have resisted implementing EBPP for fear of being unable to cross-promote other services to customers, although experts claim EBPP appears ideal for this type of marketing. The banking industry also has been resistant for fear of losing out on lucrative cash-management services, reminiscent of the battle the industry fought and lost over credit card transactions. Disputes over adopting uniform security and implementation standards also have stalled the adoption of EBPP.

The common protocol known as the Open Financial Exchange would allow firms to integrate their systems. But the protocol has not been widely embraced, especially by banks, which are concerned about possibly losing control of their vital customer information. A second competing standard also is emerging. Spectrum, a joint venture of The Chase Manhattan Corp., First Union Corp. and Wells Fargo & Co., is adopting the Interactive Financial Exchange (IFX) protocol. The IFX Forum, an organization that comprises financial institutions, billers, insurance companies and vendors, is developing IFX.

Despite these difficulties, experts predict the industry will experience a growth spurt, driven by customers who want the convenience and time savings associated with being able to access, view and remit their bills directly online.

e-brokerage

An e-brokerage is a brokerage house that allows you to buy and sell stocks and obtain investment information from its Web site. Some e-brokerages are provided by traditional and well-established “offline” brokerage houses and a few are exclusively online only.

Traditional investing has experienced a revolution due to the rise of the e-brokerage industry, which enables investors to use the Internet to conduct secure trading. Two factors are contributing to the enormous growth of online investing. First, the Internet gives ready access to raw data. Second, investment houses can offer transactions at lower prices than traditional methods by eliminating the need for brokers or financial advisers.

The online brokerage industry has yet to attract mainstream investors, who represent 85 percent of the retail investment community. These investors prefer a combination of brokerage services, including not only online trading, but also financial advice and guidance.

Still, despite initial resistance, nearly every major investment firm offers trading with the click of a mouse. By 2003, it is estimated that about \$3 trillion will be held in online brokerage accounts. The survival of brokerage firms may depend on how quickly they identify future customers.

e-business

E-business (electronic business), derived from such terms as “e-mail” and “e-commerce,” is the conduct of business on the Internet, not only buying and selling but also servicing customers and collaborating with business partners. One of the first to use the term was IBM, when, in October 1997, it launched a thematic campaign built around the term. Today, major corporations are rethinking their businesses in terms of the Internet and its new culture and capabilities. Companies are using the Web to buy parts and supplies from other companies, to collaborate on sales promotions, and to do joint research. Exploiting the convenience, availability, and world-wide reach of the Internet, many companies, such as Amazon.com, the book sellers, have already discovered how to use the Internet successfully.

Increasingly, much direct selling (or **e-tailing**) is taking place on the Internet of computer-related equipment and software. One of the first to report sales in the millions of dollars directly from the Web was Dell Computer. Travel bookings directly or indirectly as a result of Web research are becoming significant. Custom-orderable golf clubs and similar specialties are considered good prospects for the immediate future.

With the security built into today’s browsers and with **digital certificates** now available for individuals and companies from Verisign, a certificate issuer, much of the

early concern about the security of business transaction on the Web has abated and e-business by whatever name is accelerating.

IBM considers the development of **intranets** and **extranets** to be part of e-business. e-business can be said to include *e-service*, the provision of services and tasks over the Internet by application service providers (**ASPs**).

ebXML

ebXML (Electronic Business XML) is a project to use the Extensible Markup Language (**XML**) to standardize the secure exchange of business data. Among other purposes, ebXML would encompass and perhaps replace a familiar standard called Electronic Data Interchange (**EDI**). ebXML is designed to enable a global electronic marketplace in which enterprises of any size, and in any location, could safely and securely transact business through the exchange of XML-based messages. The United Nations body for Trade Facilitation and Electronic Business Information Standards (UN/CEFACT) and the Organization for the Advancement of Structured Information Standards (**OASIS**) launched the project as a joint initiative. Its membership includes 75 companies, including major IT vendors and trade associations throughout the world.

Because ebXML relies on the Internet’s existing standards such as HTTP, TCP/IP, MIME, SMTP, FTP, UML, and XML, it can be implemented and deployed on virtually any computing platform. The use of existing standards gives ebXML the advantage of being relatively inexpensive and easy to use.

A white paper on the official ebXML Web site explains that the initiative is built on three basic concepts: (1) provide an infrastructure that ensures data communication interoperability; (2) provide a semantics framework that ensures commercial interoperability; and (3) provide a mechanism that allows enterprises to find each other, agree to become trading partners and conduct business with each other. The core infrastructure specifications of ebXML are the messaging service, the registry and repository, and the collaborative partner agreement. The messaging service specification has been developed enough to enable early development work. The registry and repository and the collaborative partner specifications are nearing completion, with the complete set of ebXML specifications expected to be finished in May 2001.

E-carrier system

To see the relationship between the E-carrier system, the **T-carrier system**, and DS0 multiples, see **digital signal X**.

E1 (or E-1) is a European digital transmission format devised by the **ITU-TS** and given the name by the Conference of European Postal and Telecommunication Administration

(CEPT). It's the equivalent of the North American **T-carrier system** format. E2 through E5 are carriers in increasing multiples of the E1 format.

The E1 signal format carries data at a rate of 2.048 million bits per second and can carry 32 channels of 64 **Kbps*** each. E1 carries at a somewhat higher data rate than T-1 (which carries 1.544 million bits per second) because, unlike T-1, it does not do *bit-robbing* and all eight bits per channel are used to code the signal. E1 and T-1 can be interconnected for international use.

E2 (E-2) is a line that carries four multiplexed E1 signals with a data rate of 8.448 million bits per second.

E3 (E-3) carries 16 E1 signals with a data rate of 34.368 million bits per second.

E4 (E-4) carries four E3 channels with a data rate of 139.264 million bits per second.

E5 (E-5) carries four E4 channels with a data rate of 565.148 million bits per second.

*In international English outside the U.S., the equivalent usage is "kbps" or "kbits s⁻¹."

eCash

See "digital cash"

ECB

See "Electronic Code Book"

ECC

ECC (either "error correction [or correcting] code" or "error checking and correcting") allows data that is being read or transmitted to be checked for errors and, when necessary, corrected **on the fly**. It differs from **parity**-checking in that errors are not only detected but also corrected. ECC is increasingly being designed into data storage and transmission hardware as data rates (and therefore error rates) increase.

Here's how it works for data storage:

1. When a unit of data (or "**word**") is stored in RAM or peripheral storage, a code that describes the bit sequence in the word is calculated and stored along with the unit of data. For each 64-bit word, an extra 7 bits are needed to store this code.
2. When the unit of data is requested for reading, a code for the stored and about-to-be-read word is again calculated using the original algorithm. The newly generated code is compared with the code generated when the word was stored.
3. If the codes match, the data is free of errors and is sent.
4. If the codes don't match, the missing or erroneous bits are determined through the code comparison and the bit or bits are supplied or corrected.

5. No attempt is made to correct the data that is still in storage. Eventually, it will be overlaid by new data and, assuming the errors were transient, the incorrect bits will "go away."
6. Any error that recurs at the same place in storage after the system has been turned off and on again indicate a permanent hardware error and a message is sent to a log or to a system administrator indicating the location with the recurrent errors.

At the 64-bit word level, parity-checking and ECC require the same number of extra bits. In general, ECC increases the reliability of any computing or telecommunications system (or part of a system) without adding much cost. Reed-Solomon codes are commonly implemented; they're able to detect and restore "erased" bits as well as incorrect bits.

E-CD

See "enhanced CD"

eCheck

An eCheck is an electronic version of a paper check. It uses the same legal and business protocols associated with traditional paper checks—it can be used in any transactions where paper checks are used today—yet it capitalizes on the speed and processing efficiencies of all-electronic payments.

The technology used to standardize the implementation of eChecks was developed by the Financial Services Technology Consortium (FSTC), whose eCheck project is currently being used by the United States Treasury in a two-year pilot program. eChecks are based on the Financial Services Markup Language (**FSML**, the markup language developed to allow eCheck technology into the marketplace.

The FSTC's eCheck technology takes the basic, and nearly ubiquitous, concept and applies it to a markup-language-based document, thereby recognizing the need for basic signing, co-signing, and countersigning or notarizing. eChecks also utilize several different state-of-the-art security techniques including **authentication**, **public key infrastructure**, and **certificate authority** in order to ensure the integrity of each electronic transaction.

The path an eCheck takes looks something like this: the payer writes the eCheck on a computer, signs it, and e-mails it over the Internet. The payee receives it, verifies signatures, endorses it, writes a deposit slip, and signs it. The endorsed check is then sent by e-mail to the payee's bank for deposit. Bank personnel verify signatures, credit the deposit, and then clear and settle the endorsed eCheck by sending it on to the payer's bank, where signatures are once again verified and the amount of the eCheck is debited from the payer's account.

The cryptographic certificates used with an eCheck enable a check payee to determine the validity of the signatures. Initially, these certificates are actually transmitted with the

eCheck, but alternative models where the transmission, or possibly even issuance, of the certificate is not required are currently in the making.

eCheck technology also allows digital signatures to be applied to document blocks, rather than to the entire document. This allows parts of a document to be separated from the original, without compromising the integrity of the digital signature.

Echelon

According to such sources as the American Civil Liberties Union (ACLU) and the British Broadcasting Corporation (BBC), Echelon is a secret U.S.-led global spy network that operates an automated system for the interception and relay of electronic communications. Monitored transmissions are said to include up to 3 billion communications daily, including all the telephone calls, e-mail messages, faxes, satellite transmissions, and Internet downloads of both public and private organizations and citizens worldwide. Led by the U.S. National Security Agency (NSA), Echelon is operated collaboratively by the intelligence agencies of the United States, the United Kingdom, Australia, Canada, and New Zealand. The organization's name originated as the code name for the system component responsible for intercepting **satellite** communications.

Echelon collects information through an extensive system of radio antennae and satellites that monitor satellite communications and **sniffer** devices that collect Internet communications from **data packets**. Some sources claim that the organization employs underwater devices to tap into transcontinental **fiber optic** phone cables. According to the ACLU, Echelon gathers huge volumes of data indiscriminately, and then filters out useful information through artificial intelligence (AI) technology. The system is also said to involve **voice recognition**, language translation, and keyword searching to select messages to study in their entirety. In October 1999, an e-mail based **hacktivism** campaign urged message recipients to include likely Echelon keywords ("manifesto," "revolution," and "Bill Clinton," for example) in any communications they sent on "Jam Echelon Day," with the intention of overwhelming the system. Because of the clandestine nature of Echelon, however, it is difficult to gauge the success of the campaign: whether or not Jam Echelon Day was effective, the organization itself has nothing to say about it—or about anything else, for that matter.

Although officials in both the United States and Britain have repeatedly denied the claims, the fact of Echelon's existence has been publicly admitted by the governments of both Australia and New Zealand. Although most people have no objection to some of Echelon's mandate (anti-terrorist surveillance, for example), many are made uneasy by claims that the organization practices economic espionage and monitors well-intentioned endeavors, such as Amnesty International. The Scientific and Technical Options

Assessment program office (STOA) of the European Parliament recently commissioned two reports looking into Echelon. These reports found: that the organization exists; that it routinely intercepts both personal and business communications, in probable contravention of human rights; and that stringent **encryption** practices should be followed to protect against Echelon's transgressive invasions of privacy.

ECMAScript

ECMAScript is a standard **script** language, developed with the cooperation of Netscape and Microsoft and mainly derived from Netscape's **JavaScript**, the widely-used scripting language that is used in Web pages to affect how they look or behave for the user. Microsoft states that its latest version of **JScript** is the first implementation of the ECMAScript standard. The official standard, ECMA-262, was developed under the auspices of the European Computer Manufacturers Association (ECMA). Having the ECMAScript standard will help ensure more consistency between Netscape, Microsoft, and any other Web script implementations.

ECMAScript is **object-oriented** and conceived as a *core language* to which can be added the objects of any specific **domain** or context such as the idea of a "document." (for example, the World Wide Web Consortium's **Document Object Model**). ECMAScript together with the Document Object Model corresponds closely to the current implementations of JavaScript and JScript. Although likely to be used mainly as a standard script language for the World Wide Web, ECMAScript could also be used for any scripted application.

e-commerce

E-commerce (electronic commerce or EC) is the buying and selling of goods and services on the Internet, especially the World Wide Web. In practice, this term and a newer term, **e-business**, are often used interchangeably. For online retail selling, the term **e-tailing** is sometimes used.

E-commerce can be divided into:

- E-tailing or "virtual storefronts" on Web sites with online catalogs, sometimes gathered into a "virtual mall"
- The gathering and use of demographic data through Web contacts
- Electronic Data Interchange (**EDI**), the business-to-business exchange of data
- **E-mail** and **fax** and their use as media for reaching prospects and established customers (for example, with newsletters)
- Business-to-business buying and selling
- The security of business transactions

E-tailing or The Virtual Storefront and the Virtual Mall

As a place for direct retail shopping, with its 24-hour availability, a global reach, the ability to interact and provide custom information and ordering, and multimedia prospects, the Web is rapidly becoming a multibillion dollar source of revenue for the world's businesses. A number of businesses already report considerable success. As early as the middle of 1997, Dell Computers reported orders of a million dollars a day. By early 1999, projected e-commerce revenues for business were in the billions of dollars and the stocks of companies deemed most adept at e-commerce were skyrocketing. Although many so-called **dotcom** retailers disappeared in the economic shakeout of 2000, Web retailing at sites such as Amazon.com, CDNow.com, and CompudataOnline.com continues to grow.

Market Research

In early 1999, it was widely recognized that because of the interactive nature of the Internet, companies could gather data about prospects and customers in unprecedented amounts -through site registration, questionnaires, and as part of taking orders. The issue of whether data was being collected with the knowledge and permission of market subjects had been raised. (Microsoft referred to its policy of data collection as "profiling" and a proposed standard has been developed that allows Internet users to decide who can have what personal information.)

Electronic Data Interchange (EDI)

EDI is the exchange of business data using an understood data format. It predates today's Internet. EDI involves data exchange among parties that know each other well and make arrangements for one-to-one (or point-to-point) connection, usually dial-up. EDI is expected to be replaced by one or more standard **XML** formats, such as **ebXML**. are

E-Mail, Fax, and Internet Telephony

E-commerce is also conducted through the more limited electronic forms of communication called e-mail, facsimile or fax, and the emerging use of telephone calls over the Internet. Most of this is business-to-business, with some companies attempting to use e-mail and fax for unsolicited ads (usually viewed as online junk mail or **spam**) to consumers and other business prospects. An increasing number of business Web sites offer e-mail newsletters for subscribers. A new trend is **opt-in e-mail** in which Web users voluntarily sign up to receive e-mail, usually sponsored or containing ads, about product categories or other subjects they are interested in.

Business-to-Business Buying and Selling

Thousands of companies that sell products to other companies have discovered that the Web provides not only a 24-hour-a-day showcase for their products but a quick way to reach the right people in a company for more information.

The Security of Business Transactions

Security includes authenticating business transactors, controlling access to resources such as Web pages for registered or selected users, **encrypting** communications, and, in general, ensuring the privacy and effectiveness of transactions. Among the most widely-used security technologies is the Secure Sockets Layer (**SSL**), which is built into both of the leading Web browsers.

e-commerce hosting

E-commerce hosting is a business in which a company provides other companies whatever they need to sell their products and services on the World Wide Web—including a **Web server** to serve a company's pages, possibly the Web site design (including catalog pages), and the special capabilities needed to accept, process, and confirm sales orders. **E-commerce hosting** usually includes providing templates for building virtual storefronts or online catalogs, providing software for customized electronic "shopping carts," taking and filling customer orders, arranging for secure credit-card purchasing, and providing tools for tracking and managing inventory.

Here's how it typically works:

A company contracts with an e-commerce hosting provider to purchase hosting space on its computer **server**. This space usually is billed monthly, along with any leasing of computer software for processing online orders. The computer server may be shared with other clients, or in the case of companies expecting a substantial amount of traffic, may be dedicated exclusively to one client.

To ensure secure payment processes, these providers also usually assist with setting up Internet merchant accounts, which are bank accounts established to process Visa, MasterCard, American Express and Discover credit-card transactions. Some hosting providers will register a company's domain name as part of the package.

E-commerce hosting firms customarily manage all the technical aspects of creating and maintaining a commercial Web site for its customers. For smaller companies, this is often more effective and cost-efficient than setting up and managing their own e-commerce site themselves since they are essentially sharing the cost of expensive equipment and Internet connections with other companies.

An e-commerce hosting provider may also provide services other than managing online transactions, including **EDI**, the gathering of demographic or other information (usually for marketing purposes), or transactions between businesses (business-to-business e-commerce).

e-copy

An e-copy is an electronic copy of a document. For example, when you send someone an **e-mail** note and specify that a copy of the note should be sent to someone else, the copy could be called an e-copy. The term does not seem to be very widely used, perhaps because, like e-mail, electronic copying is becoming so commonplace that identifying the copy as “electronic” seems unnecessary. Notice how often people today say “I’ll send you a note” or “I’ll send you some mail,” because the electronic context is understood.

Edapt

Edapt is the trade name for an e-learning (electronic learning) program developed by Tcert of Atlanta, Georgia. The software employs artificial intelligence (**AI**) to streamline the learning process for a student, and to make the program a better teacher as a student spends time with it.

Features of Edapt include an interface that keeps the student interested and helps the student follow specialized, nonlinear learning paths. The level of difficulty is constantly adjusted based on student performance, optimizing the amount of material learned per unit time. Students are given frequent opportunities to evaluate their progress. Animation, speech recognition, and interactivity enhance the flexibility of the program and keep users attentive. The learning environment has been described as structured yet not restrictive.

In a class setting, Edapt keeps track of the progress and needs of each individual student, and also of the group as a whole. Thus, the program can optimize curricula for small and large groups, as well as for individual students. Edapt is available for use in most natural languages, and most operating platforms. It can be used with individual computers, in a local area network (LAN), or on the Internet.

EDFA

See “erbium amplifier”

EDGE

EDGE (Enhanced Data GSM Environment), a faster version of the Global System for Mobile (**GSM**) wireless service, is designed to deliver data at rates up to 384 **Kbps** and enable the delivery of multimedia and other broadband applications to mobile phone and computer users. The EDGE standard is built on the existing GSM standard, using the same time-division multiple access (**TDMA**) **frame** structure and existing **cell** arrangements. Ericsson notes that its base stations can be updated with software.

EDGE is expected to be commercially available in 2001. It is regarded as an evolutionary standard on the way to Universal Mobile Telecommunications Service (**UMTS**).

edge router

A term used in asynchronous transfer mode (**ATM**) networks, an edge router is a device that routes data between one or more local area networks (**LANs**) and an **ATM backbone** network, whether a **campus** network or a wide area network (**WAN**). An edge router is an example of an *edge device* and is sometimes referred to as a *boundary router*. An edge router is sometimes contrasted with a *core router*, which forwards packets to computer hosts within a network (but not between networks).

EDI

EDI (Electronic Data Interchange) is a standard format for exchanging business data. The standard is **ANSI X12** and it was developed by the Data Interchange Standards Association. ANSI X12 is either closely coordinated with or is being merged with an international standard, EDIFACT.

An EDI message contains a string of *data elements*, each of which represents a singular fact, such as a price, product model number, and so forth, separated by **delimiter**. The entire string is called a *data segment*. One or more data segments framed by a header and trailer form a *transaction set*, which is the EDI unit of transmission (equivalent to a *message*). A transaction set often consists of what would usually be contained in a typical business document or form. The parties who exchange EDI transmissions are referred to as *trading partners*.

EDI messages can be **encrypted**. EDI is one form of **e-commerce**, which also includes **e-mail** and **fax**.

EDM

1) EDM (Electronic Document Management) is the management of different kinds of **documents** in an **enterprise** using computer programs and storage. An EDM system allows an enterprise and its users to create a document or capture a hard copy in electronic form, store, edit, print, process, and otherwise manage documents in **image**, video, and **audio**, as well as in **text** form. An EDM system usually provides a single view of multiple **databases** and may include **scanners** for document capture, printers for creating hard copy, storage devices such as **redundant array of independent disks** systems, and computer **server** and server programs for managing the databases that contains the documents.

EDM may be needed in enterprises that capture and store a large number of documents such as invoices, sales orders, photographs, phone interviews, or video newsclips. EDM may be combined with or integrated into other applications. It may be combined with a **workflow** management approach. Capture may include document **imaging** and optical character recognition (**OCR**).

2) Engineering Data Management (EDM) is the management using computers and electronic storage media of documents or **data** that relate to engineering applications.

3) EDM (Electrical Discharge Machine or Machining) is a machine process driven by a computer program that is used in making high-precision molds, dies, or machine parts.

EDO RAM

EDO (extended data output) RAM is a type of random access memory (**RAM**) chip that improves the time to read from memory on faster **microprocessors** such as the Intel **Pentium**. EDO RAM was initially optimized for the 66 MHz Pentium. For faster computers, different types of synchronous dynamic RAM (**SDRAM**) are recommended.

Also see **BEDO DRAM**.

EDP

EDP (electronic data processing), an infrequently used term for what is today usually called "IS" (information services or systems) or "MIS" (management information services or systems), is the processing of **data** by a computer and its programs in an environment involving electronic communication. EDP evolved from "DP" (data processing), a term that was created when most computing input was physically put into the computer in punched card form and output as punched cards or paper reports.

EDRAM

EDRAM (enhanced dynamic random access memory) is **dynamic random access memory** (dynamic or power-refreshed **RAM**) that includes a small amount of static RAM (**SRAM**) inside a larger amount of DRAM so that many memory accesses will be to the faster SRAM. EDRAM is sometimes used as **L1 and L2** memory and, together with **enhanced synchronous dynamic DRAM**, is known as *cached DRAM*.

Data that has been loaded into the SRAM part of the EDRAM can be accessed by the **microprocessor** in 15 ns (nanoseconds). If data is not in the SRAM, it can be accessed in 35 ns from the DRAM part of the EDRAM.

edu

"edu" is one of the top-level **domain names** that can be used when choosing a domain name. It generally describes the entity owning the domain name as a four-year college or similar educational institution. (Educational institutions below four-year colleges are encouraged to use the geographic "us" top-level domain name.) Along with the second-level domain name (for example: "umich" in umich.edu), the top-level domain name is required in Web and e-mail addresses.

For more information, see **gTLD** (generic top-level domain name).

edutainment

Edutainment is a **neologism** (new term coinage), similar to **infotainment**, that expresses the marriage of education and entertainment in a work or presentation such as a television program or a Web site. The most educationally effective children's programs on television (Sesame Street, The Electric Company, Mr. Rogers) could be classed as edutainment. Outstanding Web sites that "edutain" include Learn2.com and HowStuffWorks.com.

EEPROM

EEPROM (electrically erasable programmable read-only memory) is user-modifiable read-only memory (**ROM**) that can be erased and reprogrammed (written to) repeatedly through the application of higher than normal electrical voltage. Unlike **EPROM** chips, EEPROMs do not need to be removed from the computer to be modified. However, an EEPROM chip has to be erased and reprogrammed in its entirety, not selectively. It also has a limited life—that is, the number of times it can be reprogrammed is limited to tens or hundreds of thousands of times. In an EEPROM that is frequently reprogrammed while the computer is in use, the life of the EEPROM can be an important design consideration.

A special form of EEPROM is **flash memory**, which uses normal PC voltages for erasure and reprogramming.

EFF

See "Electronic Frontier Foundation"

EFS

See "Encrypting File System"

EGA

See "display modes"

egosurfing

Egosurfing is looking to see how many places on the Web your name appears. On Alta Vista, you can also see how many times it appears in **Usenet** postings. On Alta Vista (<http://www.altavista.com>) and most other search engines, simply enter your name surrounded by double quotes in the search field like this:

"Your Name"

and you may be surprised to discover that you're a celebrated personage on someone's Web page or that the local task force report you helped write got put on the Web.

Egosurfing is also a way to find out how many of your site's Web pages are either indexed by the search engine or referred to by other sites. Just enter your second-level domain name, enclosed in quotes, like this:

"whatis.com" (but enter your own domain name)

e-government

See “B2C”

EGP

See “Exterior Gateway Protocol”

egress

Egress (pronounced EE-grehs, from Latin *egressus*, or going out) is the act of going out of something. For example, in telecommunications, an egress router is a router through which a data packet leaves one network for another network.

EIA

1) The Electronic Industries Association (EIA) comprises individual organizations that together have agreed on certain data transmission standards such as EIA/TIA-232 (formerly known as **RS-232**).

2) The Electronics Industries Alliance (EIA) is an alliance of trade organizations that lobby in the interest of companies engaged in the manufacture of electronics-related products.

EIDE

Enhanced (sometimes “Expanded”) IDE is a standard electronic interface between your computer and its mass storage drives. EIDE’s enhancements to Integrated Drive Electronics (**IDE**) make it possible to address a hard disk larger than 528 Mbytes. EIDE also provides faster access to the hard drive, support for Direct Memory Access (**DMA**), and support for additional drives, including CD-ROM and tape devices through the AT Attachment Packet Interface. When updating your computer with a larger hard drive (or other drives), an EIDE “controller” can be added to your computer in one of its **card slot**.

To access larger than 528 Mbyte drives, EIDE (or the **basic input/output system** that comes with it) uses a 28-bit logical block address (**LBA**) to specify the actual cylinder, head, and sector location of data on the disk. The 28 bits of the LBA provide enough information to specify unique sectors for a device up to 8.4 GB in size.

EIDE was adopted as a standard by **ANSI** in 1994. ANSI calls it Advanced Technology Attachment-2 (it’s also referred to as “Fast **ATA**”).

Also see **IDE**.

Eiffel

Eiffel is an **object-oriented** programming language developed by Bertrand Meyer, owner of Interactive Software Engineering (ISE), and named after Gustave Eiffel, the engineer who designed the Eiffel Tower. ISE Eiffel encompasses the Eiffel language, a method, and a programming environment. The language itself includes

analysis, design, and implementation tools and was designed to create reusable code and to be **scalable**. The idea is that reusable components make writing programs more efficient because they save programming time and increase reliability. **Scalability** enables initially small programs to be expanded later to meet new needs. Eiffel is available for use on all major platforms.

Eiffel was designed to be simple, easy to learn, and powerful. It has the ability to incorporate program elements written in other languages. Features of Eiffel include **classes**, multiple **inheritance**, **polymorphism**, and a disciplined exception mechanism. ISE claims that Eiffel enables the fast production of bug-free software that is easy to change and extend in response to user requests, and can be reused in many different applications.

EIGRP

EIGRP (Enhanced Interior Gateway Routing Protocol) is a network **protocol** that lets **routers** exchange information more efficiently than with earlier network protocols. EIGRP evolved from IGRP (Interior Gateway Routing Protocol) and routers using either EIGRP and IGRP can interoperate because the **metric** (criteria used for selecting a route) used with one protocol can be translated into the metrics of the other protocol. EIGRP can be used not only for Internet Protocol (**IP**) networks but also for and Novell **NetWare** networks.

Using EIGRP, a router keeps a copy of its neighbor’s routing tables. If it can’t find a route to a destination in one of these tables, it queries its neighbors for a route and they in turn query their neighbors until a route is found. When a routing table entry changes in one of the routers, it notifies its neighbors of the change only (some earlier protocols require sending the entire table). To keep all routers aware of the state of neighbors, each router sends out a periodic “hello” packet. A router from which no “hello” packet has been received in a certain period of time is assumed to be inoperative.

EIGRP uses the Diffusing-Update Algorithm (**DUAL**) to determine the most efficient (*least cost*) route to a destination. A **DUAL finite state machine** contains decision information used by the algorithm to determine the least-cost route (which considers distance and whether a destination path is loop-free).

EIP

See “enterprise information portal”

EISA

EISA is a standard **bus** (computer interconnection) architecture that extends the **ISA** standard to a 32-bit interface. It was developed in part as an open alternative to the proprietary Micro Channel Architecture (**MCA**) that IBM introduced in its PS/2 computers.

#

EISA data transfer can reach a peak of 33 megabytes per second.

A

EJB

See "Enterprise JavaBeans"

B

C

electric field strength

Electric field strength is a quantitative expression of the intensity of an electric field at a particular location. The standard unit is the **volt per meter** (v/m or $v \cdot m^{-1}$). A field strength of $1 v/m$ represents a potential difference of one **volt** between points separated by one meter.

D

E

Any electrically charged object produces an electric field. This field has an effect on other charged objects in the vicinity. The field strength at a particular distance from an object is directly proportional to the electric charge, in **coulombs**, on that object. The field strength is inversely proportional to the distance from a charged object. The field-strength-vs-distance curve is a direct inverse function, and not an inverse-square function, because electric field strength is specified in terms of a linear displacement (per meter) rather than a surface area (per meter squared).

F

G

H

I

J

An alternative expression for the intensity of an electric field is **electric flux density**. This refers to the number of lines of electric **flux** passing orthogonally (at right angles) through a given surface area, usually one **meter squared** ($1 m^2$). Electric flux density, like electric field strength, is directly proportional to the charge on the object. But flux density diminishes with distance according to the inverse-square law, because it is specified in terms of a surface area (per meter squared) rather than a linear displacement (per meter).

K

L

M

N

Sometimes the strength of an electromagnetic field (**EM field**) is specified in terms of the intensity of its electric-field component. This is done by engineers and scientists when talking about the radio-frequency field strength at a certain location arising from sources such as distant transmitters, celestial objects, high-tension utility lines, computer displays, or microwave ovens. In this context, electric field strength is usually specified in microvolts per meter ($\mu V/m$ or $\mu V \cdot m^{-1}$), nanovolts per meter (nV/m or $nV \cdot m^{-1}$), or picovolts per meter (pV/m or $pV \cdot m^{-1}$). The relationship among these units is shown in the table.

O

P

Q

R

S

Unit	To convert to v/m, multiply by:	Conversely, multiply by:
v/m	1	1
$\mu V/m$	10^{-6}	10^6
nV/m	10^{-9}	10^9
pV/m	10^{-12}	10^{12}

electrically erasable programmable ROM

See "EEPROM"

Electrohippies Collective

The Electrohippies Collective is an international group of **hacktivists** based in Oxfordshire, England, whose purpose is to express its displeasure with the use of the Internet "as a tool for corporate communications and propaganda." A common form of protest used by The Electrohippies Collective is the Web sit-in. The group organizes volunteers who repeatedly access a target's Web site or who organize a **distributed denial-of-service attack**. There is some debate as to whether actions such as this are illegal. While The Electrohippies Collective agrees that DDoS attacks violate the First Amendment of the U.S. Constitution, the group is also relentless in identifying targets and fostering attacks.

electromagnetic field

An electromagnetic field, sometimes referred to as an EM field, is generated when charged particles, such as **electrons**, are accelerated. All electrically charged particles are surrounded by electric fields. Charged particles in motion produce magnetic fields. When the velocity of a charged particle changes, an EM field is produced.

Electromagnetic fields were first discovered in the 19th century, when physicists noticed that electric arcs (sparks) could be reproduced at a distance, with no connecting wires in between. This led scientists to believe that it was possible to communicate over long distances without wires. The first radio transmitters made use of electric arcs. These "spark transmitters" and the associated receivers were as exciting to people in the early 20th century as the Internet is today. This was the beginning of what we now call **wireless** communication.

Electromagnetic fields are typically generated by alternating current (**AC**) in electrical conductors. The **frequency** of the AC can range from one cycle in thousands of years (at the low extreme) to trillions or quadrillions of cycles per second (at the high extreme). The standard unit of EM frequency is the **hertz**, abbreviated Hz. Larger units are often used. A frequency of 1,000 Hz is one **kilohertz** (kHz); a frequency of 1,000 kHz is one **megahertz** (MHz); a frequency of 1,000 MHz is one **gigahertz** (GHz).

The **wavelength** of an EM field is related to the frequency. If the frequency f of an EM wave is specified in megahertz and the wavelength w is specified in meters (m), then in free space, the two are related according to the formula

$$w = 300/f$$

For example, a signal at 100 MHz (in the middle of the American **FM** broadcast band) has a wavelength of 3 m, or about 10 feet. This same formula applies if the frequency is

given in gigahertz and the wavelength is specified in millimeters (mm). Thus, a signal at 30 GHz would have a wavelength of 10 mm, or a little less than half an inch.

The realm of EM field energy is called the **electromagnetic radiation spectrum**. In theory, this extends from arbitrarily long wavelengths to arbitrarily short wavelengths, or, as engineers sometimes imprecisely quip, “from DC to light.”

electromagnetic interference

See “EMI”

electromagnetic radiation spectrum

The electromagnetic radiation spectrum is the complete range of the **wavelengths** of electromagnetic radiation, beginning with the longest radio waves (including those in the audio range) and extending through visible light (a very small part of the spectrum) all the way to the extremely short gamma rays that are a product of radioactive **atoms**.

Electromagnetic radiation results from the physics of the **electromagnetic field**.

electron

An electron is a negatively charged subatomic particle. It can be either free (not attached to any atom), or bound to the nucleus of an **atom**. Electrons in atoms exist in spherical shells of various radii, representing energy levels. The larger the spherical shell, the higher the energy contained in the electron.

In electrical conductors, **current** flow results from the movement of electrons from atom to atom individually, and from negative to positive electric poles in general. In semiconductor materials, current also occurs as a movement of electrons. But in some cases, it is more illustrative to envision the current as a movement of electron deficiencies from atom to atom. An electron-deficient atom in a semiconductor is called a **hole**. Holes “move” from positive to negative electric poles in general.

The charge on a single electron is considered as the unit electrical charge. It is assigned negative polarity. The charge on an electron is equal, but opposite, to the positive charge on a proton or hole. Electrical charge quantity is not usually measured in terms of the charge on a single electron, because this is an extremely small charge. Instead, the standard unit of electrical charge quantity is the coulomb, symbolized by C, representing about 6.24×10^{18} electrons. The electron charge, symbolized by e , is about 1.60×10^{-19} C. The mass of an electron at rest, symbolized m_e , is approximately 9.11×10^{-31} kilogram (kg). Electrons moving at an appreciable fraction of the speed of light, for example in a particle accelerator, have greater mass because of relativistic effects.

electronic bill presentment and payment

See “EBPP”

Electronic Code Book

Also see **cryptography**.

Electronic Code Book (ECB) is a mode of operation for a **block cipher**, with the characteristic that each possible block of **plaintext** has a defined corresponding **ciphertext** value and vice versa. In other words, the same plaintext value will always result in the same ciphertext value. Electronic Code Book is used when a volume of plaintext is separated into several blocks of data, each of which is then encrypted independently of other blocks. In fact, Electronic Code Book has the ability to support a separate **encryption key** for each block type.

However, Electronic Code Book is not a good system to use with small block sizes (for example, smaller than 40 bits) and identical encryption modes. This is because some words and phrases may be reused often enough so that the same repetitive part-blocks of ciphertext can emerge, laying the groundwork for a codebook attack where the plaintext patterns are fairly obvious. However, security may be improved if random pad bits are added to each block. On the other hand, 64-bit or larger blocks should contain enough unique characteristics (entropy) to make a codebook attack unlikely to succeed.

In terms of error correction, any bit errors in a ciphertext block affect decryption of that block only. Chaining dependency is not an issue in that reordering of the ciphertext blocks will only reorder the corresponding plaintext blocks, but not affect decryption.

Electronic Data Interchange

See “EDI”

electronic data processing

See “EDP”

Electronic Frontier Foundation

The Electronic Frontier Foundation is the primary watchdog for the preservation of civil liberties on the Internet. During its “Blue Ribbon” campaign in support of free speech on the Web, it was one of the four most-visited sites on the Web, according to Webcrawler. It develops positions on free speech, encryption, privacy, and intellectual property and lobbies for them.

The EFF was founded in 1990 by John Perry Barlow, Mitch Kapor (founder of Lotus 1-2-3), and others. Membership is open to the public.

Electronic Funds Transfer

Electronic Funds Transfer (EFT) is a system of transferring money from one bank account directly to another without any paper money changing hands. One of the most widely-used EFT programs is Direct Deposit, in which payroll is

deposited straight into an employee's bank account, although EFT refers to any transfer of funds initiated through an electronic terminal, including credit card, ATM, Fedwire and point-of-sale (POS) transactions. It is used for both credit transfers, such as payroll payments, and for debit transfers, such as mortgage payments.

Transactions are processed by the bank through the Automated Clearing House (ACH) network, the secure transfer system that connects all U.S. financial institutions. For payments, funds are transferred electronically from one bank account to the billing company's bank, usually less than a day after the scheduled payment date.

The growing popularity of EFT for online bill payment is paving the way for a paperless universe where checks, stamps, envelopes, and paper bills are obsolete. The benefits of EFT include reduced administrative costs, increased efficiency, simplified bookkeeping, and greater security. However, the number of companies who send and receive bills through the Internet is still relatively small.

The U.S. Government monitors EFT compliance through Regulation E of the Federal Reserve Board, which implements the Electronic Funds Transfer Act (EFTA). Regulation E governs financial transactions with electronic payment services, specifically with regard to disclosure of information, consumer liability, error resolution, record retention, and receipts at electronic terminals.

Electronic Industries Alliance

See "EIA"

Electronic Industries Association

See "EIA"

electronic ink

Electronic ink is a liquid substance, in development at MIT's Media Lab in partnership with a company called E Ink, that responds to electrical impulses to enable changeable text and image displays on a flexible surface. Electronic ink will be used for applications such as **e-books**, **electronic newspapers**, portable signs, and foldable, rollable displays. Electronic ink consists of millions of tiny capsules filled with dark dyes and containing negatively charged white chips, floating in a substance like vegetable oil. With a printer-like device, the electronic ink-coated material—which, according to researchers, could be just about any flat surface—is subjected to electrical impulses that act upon the white chips to make them display as light or dark-colored. A positive charge applied to an area on the top of the display medium causes the white chips to float to the top surface, and a charge applied to an area on the bottom of the medium causes them to drop to the bottom. The pattern of charges applied in concert enables the display of images and text.

Information to be displayed is downloaded through a connection to a computer or a cell phone, or created with mechanical tools such as an electronic "pencil."

Lucent and E Ink are developing a device (also called **E Ink**) that uses electronic ink and combines thin, plastic, **flexible transistors** with **polymer LEDs** (**light-emitting diodes**) to create what are called **smart pixels**. The process involved—which is not dissimilar to traditional printing processes—uses silicon rubber stamps to actually print tiny computer circuits onto the surface. Electronic ink has been used for simple displays, such as retail signs. Researchers say that more complex displays using the technology are still several years away.

Displays written in electronic ink are bi-stable: they remain fixed until another charge is applied to change them. Once you had read the first section of your electronic newspaper you would select the next section that you wanted to read, download it from a wireless Internet connection and have the paper automatically refreshed to display, for example, the arts or sports news that you wanted to read. Another expected application of electronic ink is a more book-like version of the e-book. Consisting of a similar number of e-paper pages, and having the same look and feel as a traditional book, the future technology would allow the reader to download book after book to the same physical device. E Ink claims that a device written with electronic ink could be rewritten as many as 300 million times.

electronic newspaper

An electronic newspaper is a self-contained, reusable, and refreshable version of a traditional newspaper that acquires and holds information electronically. (The electronic newspaper should not be confused with newspapers that offer an online version at a Web site.) The near-future technology—researchers expect to have the product available as soon as 2003—will use **e-paper** (electronic paper) as the major component. Information to be displayed will be downloaded through a **wireless** Internet connection. A number of versions of the future technology are in development, although there are two frontrunners: Xerox's Palo Alto Research Center (PARC) is working on a newspaper that would consist of a single sheet of their e-paper (called **Gyricon**), while Lucent, in partnership with a company called E Ink, is working on a multi-page device (also called **E Ink**).

The Gyricon version consists of a single sheet of transparent plastic, containing millions of tiny bichromal (two color) beads in oil-filled pockets. Text and images are displayed through rotation of the beads that occurs in response to electrical impulses: a full rotation displays as black or white, and a partial rotation displays as gray shades. Nick Sheridan, a senior research fellow at PARC, has been working towards a viable electronic newspaper for over twenty years. Sheridan sees Xerox's device as consisting of a sheet of Gyricon wound around a spring mechanism in a

lightweight cylinder. The user would pull the page out of a slit in the cylinder; in the process, the page would pass over a printer-like device which had downloaded data from the Internet through a wireless connection. To access another page, the reader would return the sheet to the cylinder, select the page, and draw the sheet from the scroll. The device could be carried like an umbrella, and would fit in a large purse or a briefcase. Sheridan projects that a Gyricon-based electronic newspaper could be available within three years. Currently, Gyricon uses 50-micron beads for a resolution of 200 dpi (dots per inch); the use of 30-micron beads will increase resolution to 300 dpi, slightly better than that of traditional newspapers.

Lucent's E Ink device uses **electronic ink** and combines thin, plastic, **flexible transistors** with **polymer LEDs (light-emitting diodes)** to create what are called **smart pixels**. The process involved—which is not dissimilar to traditional printing processes—uses silicon rubber stamps to actually print tiny computer circuits onto the surface. E Ink uses electronic ink for display: Millions of tiny capsules filled with light and dark dyes that change color—charged dye particles move either up or down within the capsules—when exposed to an electric charge. According to Paul Drzaic, the director of display technologies, prototypes of the device have been running on watch batteries. Although the technology has been used for retail signs, Lucent says that an E Ink-based electronic newspaper is still at least 10 years away, because electronic ink has not been sufficiently developed to make complex displays practical.

IBM is also working on an electronic ink-based device. IBM's electronic newspaper is in a book-like format, and is constructed of 16 pages of flexible, fiberglass-reinforced paper, each about 8.5" by 11". The lightweight pages are bound by a rigid metallic bar, and covered with a clear, protective cover sheet. Charged dye particles move either up or down within the capsules—causing light or dark areas to appear in the display—when exposed to an electric charge. The whole device could be rolled or folded similarly to a traditional newspaper. Like the E Ink-based electronic newspaper, IBM's version is several years away.

The challenge involved in creating a viable electronic newspaper is to develop a device that has the desirable characteristics of traditional paper in addition to its own inherent benefits (such as being automatically refreshable). Like traditional paper, the electronic newspaper must be lightweight, flexible, high-resolution, glare-free, and affordable, if it is to gain consumer approval. Sheridan proposes that the Gyricon version could cost about the same as a year's subscription to a regular newspaper.

electronic paper

See "e-paper"

electronic postmaster

An electronic postmaster is the capability in a program, usually a special program designated as an **e-mail** server, for handling the distribution, forwarding, and receiving of e-mail in a network. For example, an **Simple Mail Transfer Protocol** server at your access provider acts as an electronic postmaster by forwarding your outgoing messages to their destinations in the network and by collecting your incoming messages so that you can request them from a **POP3** server that holds your messages until you request that they be sent to your workstation client.

When you send a message with an e-mail address that can't be located, the term "electronic postmaster" may appear in the message sent to you by the SMTP server.

Electronic Signatures in Global and National Commerce Act

The Electronic Signatures in Global and National Commerce Act (often referred to as the e-signature bill) specifies that in the United States, the use of a **digital signature** is as legally valid as a traditional signature written in ink on paper. In effect since October 1, 2000, the U.S. law is expected to save companies that use e-signatures a significant amount of money by reducing the costs of mailing and handling hard-copy contracts and similar documents.

The Act does not specify a single digital signature technology. Many e-signature advocates expect that the public key infrastructure (**PKI**), used for authenticating credit card transactions over the Web, will play an important role in the development of secure e-signatures. Several third-party companies are now exploring other methods to verify a person's legal identity, including the use of personal smart cards, **PDA** encryption devices, and biometric verifications (fingerprint, voice, or iris scans). Experts agree that until the legality of e-signatures has been tested in the courts, the routine use of e-signatures is likely to be several years away, primarily because businesses lack confidence in present security and verification procedures.

electronic voting

See "e-voting"

Electronic Worldwide Switch Digital

See "EWSD"

electrostatic field

See also **dielectric material**.

When two objects in each other's vicinity have different electric charges, an electrostatic field exists between them. An electrostatic field also forms around any single object that is electrically charged with respect to its environment. An object is negatively charged (-) if it has an excess of

electrons relative to its surroundings. An object is positively charged (+) if it is deficient in electrons with respect to its surroundings.

Electrostatic fields bear some similarity to magnetic fields. Objects attract if their charges are of opposite polarity (+/-); objects repel if their charges are of the same polarity (+/+ or -/-). The lines of *electrostatic flux* in the vicinity of a pair of oppositely charged objects are similar to lines of *magnetic flux* between and around a pair of opposite magnetic poles. In other ways, electrostatic and magnetic fields differ. Electrostatic fields are blocked by metallic objects, while magnetic fields can pass through most (but not all) metals. Electrostatic fields arise from a potential difference or **voltage** gradient, and can exist when charge carriers, such as electrons, are stationary (hence the “static” in “electrostatic”). Magnetic fields arise from the movement of charge carriers, that is, from the flow of **current**.

When charge carriers are accelerated (as opposed to moving at constant velocity), a fluctuating magnetic field is produced. This gives rise to a fluctuating electric field, which in turn produces another varying magnetic field. The result is a “leapfrog” effect, in which both fields can propagate over vast distances through space. Such a synergistic field is known as an **electromagnetic field**, and is the phenomenon that makes **wireless** communications, broadcasting, and control systems possible.

elegant solution

The word *elegant*, in general, is an adjective meaning of *fine quality*. Refinement and simplicity are implied, rather than fussiness, or ostentation. An elegant solution, often referred to in relation to problems in disciplines such as mathematics, engineering, and programming, is one in which the maximum desired effect is achieved with the smallest, or simplest effort. Engineers, for example, seek the elegant solution as a means of solving a problem with the least possible waste of materials and effort. The elegant solution is also likely to be accomplished with appropriate methods and materials—according to the Elegant Solution Organization, duct tape is not likely to be part of an elegant solution, unless, of course, the problem involves taping ducts.

ELF

ELF (extremely low frequency) refers to an **electromagnetic field** having a frequency much lower than the frequencies of signals typically used in communications. The most common ELF field is radiated by utility power lines. In the U.S., this frequency is 60 Hz. You are exposed to these fields whenever you are near electrical appliances of any kind.

In recent years, ELF fields have become a subject of concern in computing applications where cathode-ray tube (CRT) displays are used. These displays, typically used in desktop computer workstations and television sets, generate

electromagnetic fields because of the strong, fluctuating currents in the electron-beam deflecting coils. The frequencies of these fields are on the order of a few kilohertz or less. Some studies suggest that ELF fields might have detrimental health effects on humans exposed to them for long periods of time. The claims vary from increased risk of cancer to premature births and miscarriages. However, as of this writing, conclusive proof has yet to be obtained that ELF fields are harmful at the levels encountered by computer users.

The ELF fields surrounding a CRT display tend to be stronger off the sides of the CRT than directly in front of it or behind it. The fields diminish rapidly in intensity with increasing distance from the CRT. As a general rule, computer users should sit at least 18 inches away from a CRT display. Side-by-side workstations should be at least five feet apart. These considerations are important for visual comfort and “breathing room” as much as for minimizing the potential risk posed by ELF fields.

Elm

Elm is a popular **e-mail** program for users of **UNIX**-based operating systems. Users of a UNIX-based system’s non-graphical **shell** interface can enter the “elm” command to see menus from which they can choose to see their incoming mail or to create outgoing mail. Designed to run with **sendmail**, `/bin/rmail`, or any other Unix mail transport agent, elm includes programs like “frm” to show a table of contents of mail, and “printmail” to paginate mail files for printouts.

Originally developed by Dave Taylor, Elm is now developed by a cooperative of volunteers, called the Elm Development Group. Elm is freely distributable software. Its copyright is held by the USENET Community Trust, which assures that it is available to everyone.

EM field

See “electromagnetic field”

Emacs

Emacs (pronounced EE-maks and sometimes spelled “emacs” or “EMACS”) is a popular **text editor** used mainly on **UNIX**-based systems by programmers, scientists, engineers, students, and system administrators. Like other UNIX text editors, Emacs provides typed commands and special key combinations that let you add, delete, insert, and otherwise manipulate words, letters, lines, and other units of text. Emacs is commonly used to enter the source statements for programs. Emacs itself is built using the **Lisp** programming language and users are invited to extend or personalize it using the same language. Emacs also offers a number of convenient capabilities such as the ability to initiate a program **compiler** and to handle e-mail from within the editor.

Emacs (derived from Editing **MACRO**S) was created by Richard Stallman at MIT. A popular version is called **GNU Emacs**. Emacs offers a much longer list of commands than the other widely-used UNIX text editor, **vi** and the ability to extend the interface. Like **vi**, the full capabilities of Emacs require a considerable investment in learning (or relearning if you don't use them continually). However, a beginning set of commands makes it possible to get to work immediately.

One or more versions of Emacs have been developed for use on Windows operating systems. A reader suggests another possible derivation for the letters in Emacs: Escape-Meta-Alt-Control-Shift—apparently referring to its use of key combination commands.

e-mail

E-mail (electronic mail) is the exchange of computer-stored messages by telecommunication. (Some publications spell it *email*; we prefer the currently more established spelling of *e-mail*.) E-mail messages are usually encoded in **ASCII** text. However, you can also send non-text files, such as graphic images and sound files, as attachments sent in **binary** streams. E-mail was one of the first uses of the Internet and is still the most popular use. A large percentage of the total traffic over the Internet is e-mail. E-mail can also be exchanged between **online service provider** users and in networks other than the Internet, both public and private.

E-mail can be distributed to lists of people as well as to individuals. A shared distribution list can be managed by using an **e-mail reflector**. Some mailing lists allow you to subscribe by sending a request to the mailing list administrator. A mailing list that is administered automatically is called a **list server**.

E-mail is one of the protocols included with the Transport Control Protocol/Internet Protocol (**TCP/IP**) suite of protocols. A popular protocol for sending e-mail is **Simple Mail Transfer Protocol** and a popular protocol for receiving it is **POP3**. Both Netscape and Microsoft include an e-mail utility with their Web browsers.

e-mail rage

E-mail rage is the online equivalent of "road rage"—in fact, the new social disorder is sometimes referred to as "road rage on the information superhighway." E-mail's immediacy and informal nature have made it a unique medium for messages: Communications are sent without the time for consideration involved in traditional written letters, and without the inhibiting social factors involved in face-to-face communication. In an Internet discussion group, sending a message under the influence of **e-mail** rage is sometimes called **flaming**.

As in incidents of road rage, e-mail rage happens when people are in an environment where they may tend to respond reflexively, rather than to stop and consider how to effectively react to a given situation. Also as with episodes of

road rage, e-mail rage can quickly escalate if the parties communicating both get caught up in the emotion, as the recipient of an offensive or angry e-mail can all too easily hit the "reply" button and have an irate response back to the sender within seconds. Although e-mail rage is less likely than road rage to result in actual physical carnage, careers and reputations have certainly been damaged by it and, at the very least, time has been taken up unnecessarily.

To avoid falling prey to e-mail rage, some experts advise that you should wait a while before sending—or replying to—an angry message, and always try to express yourself without resorting to abusive language.

e-mail reflector

An e-mail reflector is a program that acts as the forwarding broadcaster of e-mail messages to the names on a distribution list. Here's how it works:

1. One member of the distribution list composes an e-mail message or replies to one.
2. The user sends the message to the e-mail reflector (which to the user usually appears to be the list itself) on the server of whomever is managing the e-mail reflector.
3. The e-mail reflector receives the message and automatically forwards a copy to each person on the distribution list.

The advantage is that the distribution list can be centrally managed so that everyone will always have the most up-to-date version. Some Internet server products come with an e-mail reflector utility.

e-mail virus

An e-mail virus is computer code sent to you as an **e-mail** note attachment which, if activated, will cause some unexpected and usually harmful effect, such as destroying certain files on your hard disk and causing the attachment to be remailed to everyone in your address book. Although not the only kind of computer **virus**, e-mail viruses are the best known and undoubtedly cause the greatest loss of time and money overall. The best two defenses against e-mail viruses for the individual user are (1) a policy of never opening (for example, double-clicking on) an e-mail attachment unless you know who sent it and what the attachment contains, and (2) installing and using **anti-virus software** to scan any attachment before you open it. (However, some e-mail viruses may be so new when you receive them that your anti-virus software may not yet be familiar with it.) Business **firewall** servers also attempt, but not always successfully, to filter out e-mail that may carry a virus attachment.

The **Melissa virus macro virus** and the **ILOVEYOU virus** are among the best publicized of recent e-mail viruses. Each of these also spawned copycat variations with different words in the subject line.

Microsoft has been criticized for allowing its widely-used Outlook e-mail program to be so easily exploited by virus creators. Some users indicate that other e-mail programs such as Eudora offer the user more protection.

emanation monitoring

See "Tempest"

embedded systems programming

Embedded systems programming is the development of programs intended to be part of a larger **operating system** or, in a somewhat different usage, to be incorporated on a microprocessor that can then be included as part of a variety of hardware devices.

EME

See "moonbounce"

EMF

EMF (Enhanced MetaFile) and raw are terms for **spool** file formats used in printing by the Windows **operating system**. When a print job is sent to the **printer**, if it is already printing another file, the computer reads the new file and stores it, usually on the **hard disk** or in **memory**, for printing at a later time. Spooling allows multiple print jobs to be given to the printer at one time.

The EMF format is the 32-bit version of the original Windows **metafile** (WMF) format. The EMF format was created to solve the deficiencies of the WMF format in printing graphics from sophisticated graphics programs. The EMF format is device-independent. This means that the dimensions of a graphic are maintained on the printed copy regardless of the resolution in **dots per inch** of the printer. In a network, the smaller file size of the EMF format reduces network traffic. EMF is the spool file used by the Windows operating system.

A raw spool file is a one that is sent to the Windows spooler unprocessed (which is why it's called "raw"). The raw file is used to send **Postscript** commands to a Postscript printer. The Postscript commands are understood by the printer, but are just plain data to the Windows spooler. The raw format is device-dependent and slower. If printing problems occur while using the EMF format, they can sometimes be fixed by simply changing the format to "raw" in the printer Properties.

EMI

Any device or system that generates an **electromagnetic field** in the **radio frequency** spectrum has the potential to disrupt the operation of electronic components, devices, and systems in its vicinity. This phenomenon is known as *electromagnetic interference* or EMI.

The internal circuits of personal computers generate RF fields. Also, cathode ray tube (CRT) displays generate EM energy over a wide band of frequencies. These emissions can interfere with the performance of sensitive **wireless** receivers nearby. If you have a wireless receiver of any kind and use it at the same time as you operate your personal computer, you will probably hear RF noise in the receiver that originates in the PC system.

Moderate- or high-powered wireless transmitters can produce EM fields strong enough to upset the operation of electronic equipment nearby. If you live near a broadcast station or in the downtown area of a large city, you have probably experienced EMI from radio or television transmitters. Cordless telephones, home entertainment systems, computers, and certain medical devices can malfunction in the presence of strong RF fields.

Problems with EMI can be minimized by ensuring that all electronic equipment is operated with a good electrical ground system. In addition, cords and cables connecting the peripherals in an electronic or computer system should, if possible, be shielded to keep unwanted RF energy from entering or leaving. Specialized components such as line filters, **capacitors**, and **inductors** can be installed in power cords and interconnecting cables to reduce the EMI susceptibility of some systems. Before performing any modifications to equipment, contact the manufacturer for technical assistance. This is especially important if modifications might void an existing warranty, and it is imperative with medical devices of any kind.

emoticon

On the Internet in e-mail, chatting, and posted messages, an emoticon (sometimes referred to as a "smiley") is a short sequence of keyboard letters and symbols, usually emulating a facial expression, expressing a feeling that supplements the message. Most of these emoticons use several symbols to create a small face with an expression such as a smile, wink, or turned-down mouth.

One of our contributors says that to read these you can either tilt your head or turn the monitor on its side.

:)	Smile
;-)	Smile with a wink
:<)	User with mustache, smiling
:-	Mad
:-(Sad
:'(Crying

EMR-shielding

See "Tempest"

emulator

In computers, an emulator is a hardware device or a program that pretends to be another particular device or program that other components expect to interact with. For example, using a 3270 emulator, a program written to be used with the 3270 workstation can communicate with and control a **personal computer** as though it were a 3270. Typically, an emulator is provided when a popular hardware device becomes outdated and no longer marketed but **legacy applications** exist that still need to communicate with the older device. The practice of using an emulator to make an older program work with a new end-use device is called **terminal emulation**.

enantiomorph

An enantiomorph (pronounced en-ANT-i-o-morf) is a mirror image of something, an opposite reflection. The term, derived from the Greek *enantios* or "opposite," is used in a number of contexts, including architecture, molecular physics, and political theory. It is reported to also be used in computer system design.

encapsulation

In general, encapsulation is the inclusion of one thing within another thing so that the included thing is not apparent. Decapsulation is the removal or the making apparent a thing previously encapsulated.

1) In **object-oriented programming**, encapsulation is the inclusion within a program **object** of all the resources need for the object to function—basically, the **methods** and the data. The object is said to "publish its interfaces." Other objects adhere to these interfaces to use the object without having to be concerned with how the object accomplishes it. The idea is "don't tell me how you do it; just do it." An object can be thought of as a self-contained atom. The object interface consists of public methods and **instantiate** data.

2) In telecommunication, encapsulation is the inclusion of one data structure within another structure so that the first data structure is hidden for the time being. For example, a TCP/IP-formatted data **packet** can be encapsulated within an **ATM** frame (another kind of transmitted data unit). Within the context of transmitting and receiving the ATM frame, the encapsulated packet is simply a stream of bits between the ATM data that describes the transfer.

encoder

In digital audio technology, an encoder is a program that converts an audio WAV file into an **MP3** file, a highly-compressed sound file that preserves the quality of a CD recording. (The program that gets the sound selection from a CD and stores it as a WAV file on a hard drive is called a **ripper**.) An MP3 encoder compresses the WAV file so that it is about one-twelfth the size of the original digital sound file.

The quality is maintained by an algorithm that optimizes for audio perception, losing data that will not contribute to perception. The program that plays the MP3 file is called a *player*. Some audio products provide all three programs together as a package.

Encrypting File System

The Encrypting File System (EFS) is a feature of the **Windows 2000 operating system** that lets any **file** or **folder** be stored in encrypted form and decrypted only by an individual user and an authorized recovery agent. EFS is especially useful for mobile computer users, whose computer (and files) are subject to physical theft, and for storing highly sensitive data.

EFS simply makes encryption an attribute of any file or folder. To store and retrieve a file or folder, a user must request a key from a program that is built into Windows 2000.

Although an encrypting file system has existed in or been an add-on to other operating systems, its inclusion in Windows 2000 is expected to bring the idea to a larger audience.

encryption

Encryption is the conversion of data into a form, called a **ciphertext**, that cannot be easily understood by unauthorized people. *Decryption* is the process of converting encrypted data back into its original form, so it can be understood.

The use of encryption/decryption is as old as the art of communication. In wartime, a **cipher**, often incorrectly called a "code," can be employed to keep the enemy from obtaining the contents of transmissions. (Technically, a *code* is a means of representing a signal without the intent of keeping it secret; examples are Morse code and ASCII.) Simple ciphers include the substitution of letters for numbers, the rotation of letters in the alphabet, and the "scrambling" of voice signals by inverting the sideband frequencies. More complex ciphers work according to sophisticated computer algorithms that rearrange the data bits in digital signals.

In order to easily recover the contents of an encrypted signal, the correct *decryption key* is required. The key is an **algorithm** that "undoes" the work of the encryption algorithm. Alternatively, a computer can be used in an attempt to "break" the cipher. The more complex the encryption algorithm, the more difficult it becomes to eavesdrop on the communications without access to the key.

Encryption/decryption is especially important in **wireless communications**. This is because wireless circuits are easier to "tap" than their hard-wired counterparts. Nevertheless, encryption/decryption is a good idea when carrying out any kind of sensitive transaction, such as a credit-card purchase online, or the discussion of a company secret between different departments in the organization. The stronger the

cipher – that is, the harder it is for unauthorized people to break it – the better, in general. However, as the strength of encryption/decryption increases, so does the cost.

In recent years, a controversy has arisen over so-called *strong encryption*. This refers to ciphers that are essentially unbreakable without the decryption keys. While most companies and their customers view it as a means of keeping secrets and minimizing fraud, some governments view strong encryption as a potential vehicle by which terrorists might evade authorities. These governments, including that of the U.S., want to set up a *key-escrow* arrangement. This means everyone who uses a cipher would be required to provide the government with a copy of the key. Decryption keys would be stored in a supposedly secure place, used only by authorities, and used only if backed up by a court order. Opponents of this scheme argue that criminals could hack into the key-escrow database and illegally obtain, steal, or alter the keys. Supporters claim that while this is a possibility, implementing the key escrow scheme would be better than doing nothing to prevent criminals from freely using encryption/decryption.

end effector

In **robotics**, an end effector is a device or tool connected to the end of a robot arm. The structure of an end effector, and the nature of the programming and hardware that drives it, depends on the intended task.

If a robot is designed to set a table and serve a meal, then robotic hands, more commonly called grippers, are the most functional end effectors. The same or similar gripper might be used, with greater force, as a pliers or wrench for tightening nuts or crimping wire. In a **robot** designed to tighten screws, however, a driver-head end effector is more appropriate. A gripper is a hindrance in that application; the driver can be attached directly to the robot arm. The driver can be easily removed and replaced with a device that operates with similar motion, such as a bit for drilling or an emery disk for sanding.

A robot arm can accommodate only certain end-effector task modes without changes to the ancillary hardware and/or programming. It is not possible to directly replace a gripper with a screwdriver head, for example, and expect a favorable result. It is necessary to change the programming of the robot controller and use a different set of end-effector motors to facilitate torque rather than gripping force. Then the gripper can be replaced with a driver head.

Also see **eye-in-hand system** and **motion plan**.

end user

In information technology, the term *end user* is used to distinguish the person for whom a hardware or software product is designed from the developers, installers, and servicers of the product. The "end" part of the term probably derives from the fact that most information technologies

involve a chain of interconnected product components at the end of which is the “user.” Frequently, complex products require the involvement of other-than-end users such as installers, administrators, and system operators. The term *end user* thus distinguishes the user for which the product is designed from other users who are making the product possible for the end user. The term is used mostly with **mainframe** computer products and seldom with personal consumer products. Often, the term *user* would suffice.

End User License Agreement

An End User License Agreement (EULA) is a legal contract between a software application author or publisher and the user of that application. The EULA, often referred to as the “software license,” is similar to a rental agreement; the user agrees to pay for the privilege of using the software, and promises the software author or publisher to comply with all restrictions stated in the EULA. The user is asked to indicate they that “accept” the terms of the EULA by opening the shrink wrap on the application package, breaking the seal on the CD case, sending a card back to the software publisher, installing the application, executing a downloadable file, or by simply using the application. The user can refuse to enter into the agreement by returning the software product for a complete refund or clicking “I do not accept” when prompted to accept the EULA during an install.

end-of-message

See “EOM”

energy

Energy is an expression of mechanical motion, thermal heat, or electrical **power** consumed, radiated, dissipated, or stored over a period of time. The common symbol for energy is the uppercase letter *E*. The standard unit is the **joule**, symbolized by *J*. In some systems, the British thermal unit (**Btu**) is specified instead; 1 Btu = 1055 J.

One joule is the energy resulting from the equivalent of one **watt** of power manifested for a period of one second. The energy in a direct-current (**DC**) circuit is equal to the product of the **voltage** in volts, the **current** in amperes, and the **time** in seconds. In alternating current (**AC**) circuits, the expression for energy is more complex.

The common symbol for current is *I*. When a DC source of *V* volts delivers *I* amperes for *t* seconds, the energy *E* expended in joules is:

$$E = VI t$$

When a direct current of *I* amperes passes through a **resistance** of *R* ohms for *t* seconds, the energy *E* lost in joules is:

$$E = I^2 R t$$

When a DC potential difference of *V* volts appears across a component having a resistance of *R* ohms for *t* seconds, the energy *E* absorbed in joules is:

$$E = V^2 t / R$$

engine

In computer programming, *engine* is a jargon term for a program that performs a core or essential function for other programs. An engine can be a central or focal **program** in an **operating system**, subsystem, or **application program** that coordinates the overall operation of other programs. It is also used to describe a special-purpose program containing an **algorithm** that can sometimes be changed. The best known usage is the term **search engine** which uses an algorithm to search an index of topics given a search argument. A search engine is designed so that its approach to searching the index can be changed to reflect new rules for finding and prioritizing matches in the index. In **artificial intelligence**, the program that uses rules of logic to derive output from a knowledge base is called an **inference engine**.

The term connotes a comparison with mechanical engines. In 1844, Charles Babbage named his stored-program computer the **Analytical Engine**.

English system of units

See “foot-pound-second system of units”

Enhanced CD

Enhanced CD (E-CD) is a compact disc (**CD**) format that enables discs to be played on either a CD player or a multimedia-capable device, such as a **CD-i** player, or a **DVD-ROM**, or **CD-ROM** drive, where added material can be displayed. E-CD, technically known as *stamped multisession*, is used to refer to any audio CD that has CD-ROM data added. Most audio CDs use only about 60 minutes-worth of the disc’s 74 available minutes-worth of space; E-CD takes advantage of the unused space to include extra data on audio CDs. Recording artists have used E-CD technology to include video clips, artist profiles, lyrics, interviews, animation, promotional material, and even games on audio disks.

E-CD specifications are described in the **Blue Book**, a 1995 supplement to the 1988 Philips and Sony **Orange Book**, that was intended as a separate definition for stamped **multisession** disc format. Because the discs are stamped (pressed from copies of the original recording), they are not user-recordable. The Blue Book, which called the new format *CD Plus* specified two recording sessions, one for audio data and one for any other included data. Like all CD formats, Enhanced CD is based on the original **Red Book** specifications. E-CD is sometimes called *CD-Extra*, *CD-Plus*, *stamped multisession*, or simply *Blue Book format*.

E-CD format is designed to overcome the problems of *mixed-mode* CDs, which also consisted of separate tracks for audio and other data. Mixed-mode discs were often responsible for speaker damage: when a CD player tried to read the data tracks, the result was loud static. Because E-CD data and audio tracks are written in separate sessions, the data track(s) can be made invisible to the CD player, so that only the audio tracks are played.

entanglement

Entanglement is a term used in **quantum theory** to describe the way that particles of energy/matter can become *correlated* to predictably interact with each other regardless of how far apart they are.

Particles, such as photons, electrons, or qubits that have interacted with each other retain a type of connection and can be entangled with each other in pairs, in the process known as correlation. Knowing the spin state of one entangled particle—whether the direction of the spin is up or down—allows one to know that the spin of its mate is in the opposite direction. Even more amazing is the knowledge that, due to the phenomenon of **superposition**, the measured particle has no single spin direction before being measured, but is simultaneously in both a spin-up and spin-down state. The spin state of the particle being measured is decided at the time of measurement and communicated to the correlated particle, which simultaneously assumes the opposite spin direction to that of the measured particle. Quantum entanglement allows **qubits** that are separated by

incredible distances to interact with each other immediately, in a communication that is not limited to the speed of light. No matter how great the distance between the correlated particles, they will remain entangled as long as they are isolated.

Entanglement is a real phenomenon (Einstein called it "spooky action at a distance"), which has been demonstrated repeatedly through experimentation. The mechanism behind it cannot, as yet, be fully explained by any theory. One proposed theory suggests that all particles on earth were once compacted tightly together and, as a consequence, maintain a connectedness. Much current research is focusing on how to harness the potential of entanglement in developing systems for **quantum cryptography** and **quantum computing**.

In 1997, Nicholas Gisin and colleagues at the University of Geneva used entangled photons to enable simple—but instantaneous—communication over a distance of seven miles.

enterprise

In the computer industry, an enterprise is an organization that uses computers. A word was needed that would encompass corporations, small businesses, non-profit institutions, government bodies, and possibly other kinds of organizations. The term *enterprise* seemed to do the job. In practice, the term is applied much more often to larger organizations than smaller ones.

enterprise application integration

See "EAI"

enterprise information portal

The enterprise information portal (EIP) is a concept for a **Web site** that serves as a single gateway to a company's information and knowledge base for employees and possibly for customers, business partners, and the general public as well.

In one model, an EIP is made up of these elements: access/search, categorization, collaboration, personalization, expertise and profiling, application integration, and security.

- **Access/search:** Access/search allows a user to get all the information needed (but no more) in the desired context. For example, a loan officer does not need marketing information to approve a loan. An EIP makes sure the loan officer gets only the information needed.
- **Categorization:** An EIP categorizes all information so that it is delivered to the user within the context needed (think of the subject structure on Yahoo)
- **Collaboration:** An EIP allows individuals to collaborate regardless of geographical location.

- **Personalization:** The information provided to individuals using an EIP is personalized to that person's role, preferences, and habits.
- **Expertise and profiling:** Expertise and profiling is essential for the collaboration element of an EIP. Individuals within an enterprise are profiled according to their experience and competencies. If an individual needs to collaborate with others, he can choose those that are qualified for the project.
- **Application integration:** This allows individuals to deliver, access, and share information regardless of applications used.
- **Security:** This provides information to users based on security clearance. The user logs on and is given access only to information that the user is authorized to access.

Enterprise JavaBeans

Enterprise JavaBeans (EJB) is an **architecture** for setting up program **components**, written in the **Java** programming language, that run in the **server** parts of a computer network that uses the **client/server** model. Enterprise JavaBeans is built on the **JavaBeans** technology for distributing program components (which are called **Beans**, using the coffee metaphor) to **clients** in a network. Enterprise JavaBeans offers **enterprises** the advantage of being able to control change at the server rather than having to update each individual computer with a client whenever a new program component is changed or added. EJB components have the advantage of being reusable in multiple applications. To **deploy** an EJB Bean or component, it must be part of a specific application, which is called a **container**.

Originated by Sun Microsystems, Enterprise JavaBeans is roughly equivalent to Microsoft's **Component Object Model/Distributed Component Object Model** architecture, but, like all Java-based architectures, programs can be deployed across all major operating systems, not just Windows. EJB's program components are generally known as **servlets** (little server programs). The application or container that runs the servlets is sometimes called an **application server**. A typical use of servlets is to replace Web programs that use the common gateway interface (CGI) and a **Practical Extraction and Reporting Language script**. Another general use is provide an interface between Web users and a **legacy application mainframe** application and its database.

In Enterprise JavaBeans, there are two types of beans: session beans and entity beans. An entity bean is described as one that, unlike a session bean, has *persistence* and can retain its original behavior or state.

enterprise relationship management

Enterprise relationship management (ERM) is software that analyzes data it has about its customers to develop a better understanding of the customer and how the customer is

using its products and services. This kind of application may use **data mining** of its **data warehouse** or existing sales, marketing, service, finance, and manufacturing databases to generate new information about its customer relationships.

enterprise resource management

See "ERM"

enterprise resource planning

See "ERP"

enterprise risk management

Enterprise risk management (ERM) is the process of planning, organizing, leading, and controlling the activities of an organization in order to minimize the effects of risk on an organization's capital and earnings. Enterprise risk management expands the process to include not just risks associated with accidental losses, but also financial, strategic, operational, and other risks.

In recent years, external factors have fueled a heightened interest by organizations in ERM. Industry and government regulatory bodies, as well as investors, have begun to scrutinize companies' risk-management policies and procedures. In an increasing number of industries, boards of directors are required to review and report on the adequacy of risk-management processes in the organizations they administer.

Since they thrive on the business of risk, financial institutions are good examples of companies that can benefit from effective ERM. Their success depends on striking a balance between enhancing profits and managing risk.

Business risk management, holistic risk management and strategic risk management are synonyms.

enterprise server

1) An enterprise server is a computer containing programs that collectively serve the needs of an **enterprise** rather than a single user, department, or specialized application. Historically, **mainframe**-sized computers have been enterprise servers although they were not referred to as **servers** until recently. As smaller, usually **UNIX**-based servers and **Wintel** computers have become faster and have been provided with enterprise-wide program management capabilities, they also been referred to as enterprise servers. In this usage, an enterprise server is both the computer hardware and its main software, the operating system. Examples are Sun Microsystems' computers with their **UNIX**-based **Solaris** or **Linux** systems, Hewlett-Packard (HP) systems, the upper end of **Windows 2000** systems, and IBM's **iSeries** systems (the largest of which is the **zSeries 900**—formerly called the **S/390**).

2) Some companies use *enterprise server* to describe a “superprogram” that runs under the **operating system** in a computer and provides services for the system administrator and for the business **application programs** and more specialized **servers** that run in the computer. Before this usage originated, such services were sometimes considered part of the operating system itself or came in separate software packages. Originally, many services provided by an enterprise server tended to be available only on IBM or similar **mainframe** computers while less powerful computers ran specialized applications. As these smaller “server” computers (such as those from Sun Microsystems and H-P) became better adapted for business (and recently Internet) applications, the bundle of services required to manage a company-wide set of applications was renamed “the enterprise server.” More specialized servers include the **Web server**, **firewall server**, **database server**, and so forth.

enterprise storage

Enterprise storage is a centralized repository for business information that provides common data management and protection, as well as data sharing functions, through connections to numerous (and possibly dissimilar) computer systems. Developed as a solution for the **enterprise** that deals with heavy workloads of business-critical information, enterprise storage systems should be scalable for workloads of up to 300 **gigabytes** without relying on excessive cabling or the creation of subsystems. Other important aspects of the enterprise storage system are unlimited connectivity and support for all the different platforms in operation.

Enterprise storage involves the use of a storage area network (**SAN**), rather than a distributed storage system, and includes benefits such as high availability and disaster recovery, data sharing, and efficient, reliable backup and restoration functions, as well as centralized administration and remote support. Through the **SAN**, multiple paths are created to all data, so that failure of a server never results in a loss of access to critical information.

entity

In general, an entity (pronounced N-tih-tee) is an existing or real thing. The word root is from the Latin, *ens*, or being, and makes a distinction between a thing’s existence and its qualities. An entity exists and that’s all it needs to do to be an entity. The fact that something exists also seems to connote separateness from other existences or entities. In programming, engineering, and probably many other contexts, the word is used to identify units, whether concrete things or abstract ideas, that have no ready name or label. In blackboard discussions, one can draw something as yet unnamed and refer to that drawing as the representation of an “entity.” (If the entity being discussed later gets ascribed qualities and a name, reference to it as an “entity” may no longer be useful.)

In some usages, an entity is close in meaning to **object** as it is used in **object-oriented programming**.

Here are some of the usages we know of:

- 1) In the Standard Generalized Markup Language (**SGML**), an entity is a specific character string that has the effect of causing a formatting program (such as a print formatter or a Web browser—which formats for a display screen) to select and present a particular character or notation. In this usage, an entity is a certain string of characters that together specify a unique font to be selected and displayed or printed. A word was needed for such a character string and “entity” came in handy. In HTML (which is a usage of **SGML**), each special entity or character string is given a name and the entities are therefore called “named entities.”
- 2) In relation to a **database**, an entity is a single person, place, or thing about which data can be stored.
- 3) In **data modeling** (a first step in the creation of a database), an entity is some unit of data that can be classified and have stated relationships to other entities.
- 4) In the Open Systems Interconnection (**OSI**) model of network communication, an entity is an active element within a subsystem that communicates with other entities using a defined protocol.
- 5) In IBM’s **RACF** security product, an entity is a user, group, or resource that is defined to **RACF**.
- 6) In **FORTRAN**, almost every program element is referred to as an entity, such as a procedure, an operator, an interface block, an input-output unit, a symbolic constant, and a statement label.

entrepreneur

Entrepreneur, translated from its French roots, means “one who undertakes.” The term is used to refer to anyone who undertakes the organization and management of an enterprise involving independence and risk as well as the opportunity for profit.

An entrepreneur, typically, is inspired to start a business because the entrepreneur perceives a consumer need that is not being adequately filled. This area of need—sometimes called an “opportunity niche”—can usually be expressed as a problem statement, such as “There is no online resource offering support for failed Web-based entrepreneurs.” In fact, that statement was the basis for a new Web business startup recently.

entropy

Also see **Claude Shannon**.

Entropy has meanings in physics and in communications theory. More generally, entropy means a process in which order deteriorates with the passage of time. It has several special meanings in data communications.

Many scientists believe that the universe is naturally evolving toward a state of maximum entropy. The example commonly cited is the tendency for thermal differences to disappear. According to the so-called theory of entropy, everything in the universe will ultimately attain a uniform temperature. There will be no energy sources or absorbers. Stars and galaxies as we know them will cease to exist. There will be no life.

In data communications, the term entropy refers to the relative degree of randomness. The higher the entropy, the more frequent are **signaling** errors. Entropy is directly proportional to the maximum attainable data speed in bps (bits per second). Entropy is also directly proportional to **noise** and **bandwidth**. The entropy in a signal is inversely proportional to compressibility; the greater the entropy, the smaller the factor by which the data can be compressed. Entropy also refers to disorder deliberately added to data in certain **encryption** processes.

ENUM

ENUM is a standard adopted by the Internet Engineering Task Force (IETF) that uses the domain name system (DNS) to map telephone numbers to Web addresses or uniform resource locators (URL). The goal of the ENUM standard is to provide a single number to replace the multiple numbers and addresses for an individual's home phone, business phone, fax, cell phone, and e-mail.

The ENUM standard is a joint effort of Telecordia and Verisign. Every toll-free call in the United States depends on Telecordia software. Verisign is the leader in translating over 24 million **.com**, **.net**, and **.org domain names** on the Internet. Verisign is also a leader in Internet security.

environment

In computers, the term *environment* when unqualified usually refers to the combination of **hardware** and **software** in a **computer**. In this usage, the term **platform** is a synonym. We often tend to think of *environment* as short for *operating system environment*, but, with the exception of UNIX-based operating systems, the operating system usually implies an underlying hardware **microprocessor** that the operating system is designed to run on.

environment variable

An environment **variable** defines some aspect of a user's environment that can vary. Generally set during the login procedure, the environment variable establishes some component of the user's working environment, such as the **default printer**, **browser**, or text editor to be used. Because these are preset as values specific to the identified user, they save time that would be used selecting them at each login. Environment variables are used across multiple languages and operating systems to provide information to applications that may be specific to the user request.

The **UNIX shell** uses environment variables to send information about the user's environment (such as the current working directory or the terminal type, for example) to the programs being run. The variable definitions are passed on to any program that is not built into the shell, and can be consulted, or modified by the program. For example, "TERM" (environment variables are expressed as upper case by programming convention) defines the type of terminal used, "PATH" defines the directories to be searched for programs corresponding to **command** names, and "USER" defines the particular user, so that access permissions may be checked for each request.

The common gateway interface (CGI) uses environment variables that are set when the server executes the gateway program, to pass information about requests from the server to the **script**. The server sends out environment variable definitions such as "SERVER_SOFTWARE," which identifies the name and version of the responding server software; "SERVER_NAME," which identifies the server's hostname, DNS **alias**, or Internet Protocol (IP) address; and "GATEWAY_INTERFACE," which identifies the CGI specification used. These environment variables are not request-specific, and are sent with every request. Other environment variables are specific to the type of request being sent, such as "SERVER_PROTOCOL," which identifies the name and revision of the **protocol** used for the request, and "REQUEST_METHOD," which identifies the **method** used for the request.

Environmental Resource Management

Environmental Resource Management (ERM) is the concern of a global organization of environmental, health, and safety experts, known as the ERM Group, with more than 110 worldwide locations. The Group has 2,400 professionally qualified staff. They work with industrial and other clients to create sound environmental, health, and safety programs. In addition to the ERM Group, a non-profit ERM Foundation supports noteworthy projects.

EOM

EOM stands for "end of message."

People who exchange a great deal of **e-mail** sometimes write a very short message in the subject line of an e-mail note and conclude it with: (EOM). This is a little faster to send and saves the receiver from having to take the time to open the note, since the entire message is visible in the subject line. The "(EOM)" is a signal that the message is wholly contained in the subject line.

e-outsourcing

For a business, e-outsourcing is buying information technology products and services that could be furnished in-house from one or a variety of sources on the Internet. For example, an organization might hire a **Web hosting** firm to

set up and run its **Web site**, an application service provider (**ASP**) to provide specific back- and front-office applications, and an outside security firm to install and maintain a **firewall** and a virtual private network (**VPN**). In a sense, the vendors act as the IT departments for the company, which is then free to focus on its **core competency**. E-outsourcing may also be provided in a package from one vendor that provides a wide range of services from other vendors.

Usually e-outsourcing enables a business running faster than if it tried to **deploy** the same technology using in-house staff. In the evolving Internet economy, where time to market is crucial and skilled IT labor is scarce, e-outsourcing is gaining in popularity. In fact, IBM CEO Lou Gerstner forecasts that the e-outsourcing market will soar to \$55 billion in 2003 and predicts the movement will be “one of the really game-changing [IT] developments.” Gerstner is so confident in the model that IBM is investing billions in new e-business hosting centers. Other top vendors are also making significant moves to enhance their e-outsourcing offerings.

E-outsourcing isn't without potential pitfalls, though. Some firms are less than confident when it comes to giving e-outsourcers access to their sensitive data. Also, some question how much responsibility an e-outsourcer will accept when its service isn't sufficient and whether it can integrate its offerings with a business's existing infrastructure and legacy applications.

epaper

See “e-paper”

e-paper

E-paper (sometimes called *radio paper* or just *electronic paper*) is a portable, reusable storage and display medium that looks like paper but can be repeatedly written on (refreshed)—by electronic means—thousands or millions of times. E-paper will be used for applications such as **e-books**, **electronic newspapers**, portable signs, and foldable, rollable displays. Information to be displayed is downloaded through a connection to a computer or a cell phone, or created with mechanical tools such as an electronic “pencil”. There are a number of different technologies being developed: Xerox, in partnership with 3M, has created an e-paper called **Gyricon** that is expected to be marketed in the not-distant future and Lucent, in partnership with a company called E Ink, is working on a device (also called **E Ink**) that is expected to be available within the next few years. Both of these technologies enable a black (or other color) and white display; Philips is working on a type of e-paper that will be full-color, but say that the product is at least 10-15 years away.

The Gyricon version consists of a single sheet of transparent plastic, containing millions of tiny bichromal (two color) beads in oil-filled pockets. Text and images are displayed through a rotation of the beads that occurs in response to an

electrical impulse: A full rotation displays as black or white, and a partial rotation displays as gray shades. Like traditional paper, Gyricon has—and needs—no lighting component.

Lucent's E Ink device uses **electronic ink** and combines thin, plastic, **flexible transistors** with **polymer LEDs** (**light-emitting diodes**) to create what are called **smart pixels**. The process involved—which is not dissimilar to traditional printing processes—uses silicon rubber stamps to actually print tiny (as small as those for the Pentium III processor) computer circuits onto the surface. E Ink uses electronic ink for display: A liquid plastic substance consisting of millions of tiny capsules filled with light and dark dyes that change color—charged dye particles move either up or down within the capsules—when exposed to an electric charge. According to Paul Drzaic, the director of display technologies, prototypes of the device have been running on watch batteries. The E Ink technology has been used for retail signs.

Neither the Lucent/E Ink version nor the Gyricon version require a constant power source; the initial charge creates the display, which then remains fixed until another charge is applied to change it. Low power demand is an important consideration for a technology that is intended to—at least partially—supplant a power-independent, standalone application like paper. The challenge involved in creating viable e-paper is to develop a material that has the desirable characteristics of traditional paper in addition to its own intrinsic benefits (such as being automatically refreshable). Like traditional paper, e-paper must be lightweight, flexible, glare-free, and affordable, if it is to gain consumer approval. Developers of both the competing e-papers claim to have accomplished most of these qualities in their products. The first e-paper products will be Gyricon-based: Portable, reusable pricing signs for stores that can be changed instantly through a computer link; the first Gyricon-based electronic newspaper is expected to be available within the next 3 years.

EPIC

EPIC (Explicitly Parallel Instruction Computing) is a 64-bit microprocessor instruction set, jointly defined and designed by **Hewlett Packard** and Intel, that provides up to 128 general and **floating point unit registers** and uses *speculative loading*, *predication*, and *explicit parallelism* to accomplish its computing tasks. By comparison, current 32-bit **CISC** and **RISC** microprocessor architectures depend on 32-bit registers, branch prediction, memory latency, and implicit parallelism, which are considered a less efficient approach in microarchitecture design.

IA-64 (Intel Architecture-64), Intel's first 64-bit CPU microarchitecture, is based on EPIC. Intel's first implementation, long expected and well-known as Merced (its code name), was christened with the **Itanium** brand name in October 1999. It is expected that Itanium-based

systems will be compatible with versions of existing and future operating systems including HP-UX, 64-bit Windows, IA-64 Linux, Project Monterey, and Novell Modesto.

EPOC

EPOC is an **operating system** designed for small, portable computer-telephones with **wireless** access to phone and other information services. EPOC is based on an earlier operating system from Psion, the first major manufacturer of personal digital assistants (PDAs). The name derived from the company's belief that the world is entering "a new epoch of personal convenience." To earlier systems, EPOC adds wireless communication and an architecture for adding application programs. Psion declared its first version of EPOC to be an **open** operating system and licensed it to other equipment makers. Psion then formed a new company with Ericsson, Nokia, and later Motorola called Symbian, which now licenses EPOC and continues to develop it. For portable equipment manufacturers, EPOC is an alternative to Microsoft's **Windows CE**. (The popular **Palm** PDA uses its own proprietary operating system, **PalmOS**.)

Symbian refers to the class of hardware EPOC serves as "wireless information devices." EPOC is a 32-bit, **multitasking** operating system that supports a pen-based graphical user interface (GUI). It is written in the C++ programming language using an **object-oriented programming** design. The code is very compact so that it can fit on a small **ROM** chip. In addition to basic services, the operating system comes with an "application suite," that includes a word processor, e-mail handler, spreadsheet program, a scheduling application, general purpose database, sketch program, world clock, voice recorder, spell checker, calculator, communication programs, and a Web browser. EPOC can be scaled from relatively large configurations for a fully-functional **handheld** computer to small configurations for **embedded systems programming** applications.

Although EPOC can be ported to other microprocessors, Symbian's preferred platform is the Advanced **RISC** Machines (ARM) architecture. Symbian considers ARM the best platform in terms of millions of instructions per second (MIPS) per watt and per dollar cost. Symbian provides development kits for C++, for OPL (a **BASIC**-like language), and for **Java**. Programmers write programs at a PC and use an emulator to test them.

EPP/ECP

EPP/ECP (Enhanced Parallel Port/Enhanced Capability Port) is a standard signaling method for bi-directional **parallel** communication between a **computer** and **peripheral** devices that offers the potential for much higher rates of data transfer than the original parallel signaling methods. EPP is for non-printer peripherals. ECP is for printers and scanners. EPP/ECP are part of **IEEE Standard 1284**, which also specifies support for current signaling methods (including

Centronics, the de facto standard for printer communication) so that both old and new peripherals can be accommodated.

The new standard specifies five modes of data transfer. Three of them support the older mono-directional modes (a forward direction method from PC to Centronics printer and two reverse direction methods from peripheral to the PC). The fourth and fifth modes, EPP and ECP, are bi-directional (**half-duplex**) signaling methods, meaning that they are designed for back-and-forth communication. Partly because these are being implemented in hardware, EPP and ECP will provide much faster data transfer. The first three methods offer an effective data transfer rate of 50 to 100 kilobytes per second. EPP and ECP offer the possibility of rates "in excess of 1 **megabyte** per second," according to Warp Nine, a chip manufacturer.

In order to get the maximum advantage of EPP/ECP, both **operating system** (or an I/O **port** controller, or both) and peripheral device must support the standard. Initially, you may get the best effect from EPP and a **Zip drive**. Even printers that support ECP are limited by the mechanical aspects of printing. Nevertheless, even users of the compatibility modes of Standard 1284 are also expected to see some benefit in data transfer to and from peripherals.

Windows operating systems have built-in support for IEEE 1284 in their parallel **plug and play** feature. Windows also supports ECP in forward direction, assuming you have a printer and a parallel port with ECP. It is likely that other vendors will provide ECP or EPP software for other operating systems.

EPP/ECP is described fully in *IEEE Std. 1284-1994 Standard Signaling Method for a Bi-Directional Parallel Peripheral Interface for Personal Computers*.

e-procurement

E-procurement is the business-to-business purchase and sale of supplies and services over the Internet. An important part of many **B2B** sites, e-procurement is also sometimes referred to by other terms, such as *supplier exchange*. Typically, e-procurement Web sites allow qualified and registered users to look for buyers or sellers of goods and services. Depending on the approach, buyers or sellers may specify prices or invite bids. Transactions can be initiated and completed. Ongoing purchases may qualify customers for volume discounts or special offers.

E-procurement software may make it possible to automate some buying and selling. Companies participating expect to be able to control parts inventories more effectively, reduce purchasing agent overhead, and improve manufacturing cycles. E-procurement is expected to be integrated with the trend toward computerized *supply chain management*.

EPROM

EPROM (erasable programmable read-only memory) is programmable read-only memory (**programmable ROM**) that can be erased and re-used. Erasure is caused by shining an intense ultraviolet light through a window that is designed into the memory chip. (Although ordinary room lighting does not contain enough ultraviolet light to cause erasure, bright sunlight can cause erasure. For this reason, the window is usually covered with a label when not installed in the computer.)

A different approach to a modifiable ROM is electrically erasable programmable read-only memory (**EEPROM**).

erbium amplifier

An erbium amplifier, also called optical amplifier or an *erbium-doped fiber amplifier* or EDFA, is an optical or IR repeater that amplifies a modulated **laser** beam directly, without opto-electronic and electro-optical conversion. The device uses a short length of optical fiber doped with the rare-earth element erbium. When the signal-carrying laser beams pass through this fiber, external energy is applied, usually at IR wavelengths. This so-called *pumping* excites the **atoms** in the erbium-doped section of optical fiber, increasing the intensity of the laser beams passing through. The beams emerging from the EDFA retain all of their original modulation characteristics, but are brighter than the input beams.

In **fiber optic** communications systems, problems arise from the fact that no fiber material is perfectly transparent. The visible-light or infrared (**IR**) beams carried by a fiber are attenuated as they travel through the material. This necessitates the use of **repeaters** in spans of **optical fiber** longer than about 100 kilometers.

A conventional repeater puts a modulated optical signal through three stages: (1) optical-to-electronic conversion, (2) electronic signal amplification, and (3) electronic-to-optical conversion. (The term *optical* encompasses IR as well as visible-light energy in this context.) Repeaters of this type limit the **bandwidth** of the signals that can be transmitted in long spans of fiber optic cable. This is because, even if a **laser** beam can transmit several gigabits per second (**Gbps**) of data, the electronic circuits of a conventional repeater cannot.

Besides eliminating complex and inefficient conversion and electronic amplification stages, the EDFA allows the transmission of signals that employ wavelength-division multiplexing (**WDM**). This increases the realizable bandwidth relative to conventional repeaters still further.

erbium-doped fiber amplifier

See "erbium amplifier"

ergonomic

The ergonomic aspect of computers deals with their usability for humans. Ergonomics is the use of research in designing systems, programs, or devices that are easy to use for their intended purposes and contexts. The terms *human factors* and *usability* are related.

erlang

Also see **Erlang programming language**, a programming language.

In telecommunications, an erlang is a number between 0 and 1 that indicates how busy a telephone facility is over a period of time. An erlang of 1 applied to a particular telephone circuit would indicate *Busy 100% of the time*. An erlang can be applied to the group of lines in a telephone **trunk** line or to the traffic in a telephone call center.

The term is named after the Danish telephone engineer, A. K. Erlang, the originator of **queueing theory**.

Erlang B is a calculation for any one of these three factors if you know or predict the other two:

- Busy Hour Traffic (BHT), or the number of hours of call traffic during the busiest hour of operation
- Blocking, or the percentage of calls that are blocked because not enough lines are available
- Lines, or the number of lines in a trunk group

An extended version of Erlang B lets you add the factor of how many people who are blocked retry their calls immediately.

Erlang C is a calculation for how many call agents (answerers) you'll need in a call center that has a given number of calls per hour, a given average duration of call, and an acceptable level of delay in answering the call.

Erlang programming language

Also see **erlang**, a unit of telephone traffic.

Erlang is a programming language designed for developing **robust** systems of programs that can be distributed among different computers in a network. Named for the Danish mathematician Agner Krarup Erlang, the language was developed by the Ericsson Computer Sciences Lab to build software for its own telecommunication products. In use for a number of years at Ericsson and other companies, Erlang is taught in over 80 universities and colleges world-wide and is freely available as **Open Source** code.

Erlang is similar to **Java** in that it uses a **virtual machine** and supports **multithreading**. However, whereas the Java development community focuses on Web applications, Erlang is aimed at the market for extremely robust servers and embedded systems.

Erlang is described as a **functional programming** language, meaning that it emphasizes the evaluation of expressions rather than the execution of commands. The expressions use functions to derive basic values. (Two other well-known programming models are *procedural* and *object-oriented*.)

Here are some features of Erlang:

- Because the location of program threads can be either explicitly specified or invisible to the program, a program can easily be distributed and run at any point in a network.
- Erlang provides dynamic **data types**, allowing programmers to develop system components (such as message dispatchers) that do not care what type of data they are handling and others that strongly enforce **data type** restrictions or that decide how to act based on the type of data they receive.
- Pattern matching allows for extremely compact and clear programs (about 5-10 times shorter than equivalent programs in C or Java).
- Like Java, Erlang provides **garbage collecting**; programmers do not have to worry about returning allocated memory space.
- Upgrades to the Erlang software don't require stopping the system.
- Interfaces to other programming languages, such as C, C++ and Java, are provided.
- Erlang comes with design patterns or templates for client-server design, state machines, event distribution, and thread supervision.
- Erlang provides a framework that supports distribution of programs across a pool of servers, with automatic recovery and redistribution whenever a server fails.
- It also includes powerful components for a network system, including an **HTTP** server, an **Simple Network Management Protocol** agent, a **Common Object Request Broker Architecture** interface, an OAM subsystem, and a fully distributed **database** engine.
- Erlang's **bytecode** is identical on all platforms, and a network of Erlang nodes may consist of any mix of NT, UNIX, or other supported platforms.
- Erlang is relatively easy to learn compared to C, C++, and Java.

The proponents of Erlang claim that it is superior to Java when developing **back-end** systems that require: fault tolerance, distributed processing, a large amount of concurrent activity, real time response times in milliseconds, and non-stop operation.

ERM

See "enterprise risk management"

ERM Group

ERM (Environmental Resource Management) Group is a global organization of environmental, health, and safety experts, with more than 110 worldwide locations. The Group has 2,400 professionally qualified staff. They work with industrial and other clients to create sound environmental, health, and safety programs. In addition to the ERM Group, a non-profit ERM Foundation supports noteworthy projects.

ERP

ERP (enterprise resource planning) is an industry term for the broad set of activities supported by multi-module application software that helps a manufacturer or other business manage the important parts of its business, including product planning, parts purchasing, maintaining inventories, interacting with suppliers, providing customer service, and tracking orders. ERP can also include application modules for the finance and human resources aspects of a business. Typically, an ERP system uses or is integrated with a **relational database** system. The deployment of an ERP system can involve considerable business process analysis, employee retraining, and new work procedures.

In a recent trend, **SAP**, Peoplesoft, and J. D. Edwards are among ERP product providers offering ERP **outsourcing**.

error checking and correcting

See "ECC"

error correction code

See "ECC"

errors

See "Internet problems"

ESCD

In personal computers with Windows, ESCD (Extended System Configuration Data) is data that provides a computer's **BIOS** and the **operating system** with information for communicating with **plug and play** (PnP) devices. Full PnP capability requires a PnP BIOS. When a computer is started, the BIOS records in the ESCD information about how older devices are configured to the system. A pre-PnP device has an inflexible configuration (for example, a specified **interrupt request** setting). PnP-attached devices can automatically be configured around the existing older configurations (or, when necessary, configured manually).

ESCON

ESCON (Enterprise Systems Connection) is a marketing name for a set of IBM and vendor products that interconnect S/390 computers with each other and with attached storage, locally attached workstations, and other devices using **optical fiber** technology and dynamically modifiable switches called ESCON Directors. In IBM mainframes, the local interconnection of hardware units is known as **channel connection** (and sometimes as local connection to distinguish it from remote or telecommunication connection). ESCON's fiber optic cabling can extend this local-to-the-mainframe network up to 60 kilometers (37.3 miles) with chained Directors. The data rate on the link itself is up to 200 **Mbps** (million bits per second) and somewhat less when adapted to the channel interface. Vendor enhancements may provide additional distance and higher amounts of throughput.

ESCON, **Fibre Channel**, and **Small Computer System Interface** are three alternative technologies used in storage area networks (**SANs**).

In the early 1990s, ESCON replaced a much slower and more cumbersome system of interconnecting mainframes and attached devices known as the bus-and-tag cable. Bus-and-tag cable was copper, used a parallel bit attachment, and is usually referred to as a parallel environment in comparing it to the ESCON environment, which uses serial bit-by-bit technology.

ESDI

ESDI (Enhanced Small Device Interface) is a hardware **interface** for a computer disk drive based on the ST-506 standard, an early industry and later **ANSI** standard based on the Seagate disk drive. ESDI improved storage capacity and data transfer rates. It was used in IBM's higher-end PS/2 computers.

ESDI has generally been supplanted by the Enhanced Integrated Drive Electronics (**EIDE**) interface and the Small Computer Systems Interface (**SCSI**).

ESDRAM

ESDRAM (enhanced synchronous DRAM), made by Enhanced Memory Systems, includes a small static RAM in the SDRAM chip. This means that many accesses will be from the faster SRAM. In case the SRAM doesn't have the data, there is a wide **bus** between the SRAM and the SDRAM because they are on the same chip. ESDRAM is the synchronous version of Enhanced Memory Systems' **EDRAM** architecture. Both EDRAM and ESDRAM devices are in the category of **cache DRAM** and are used mainly for **L1 and L2**.

ESDRAM is apparently competing with **DDR SDRAM** as a faster SDRAM chip for **Socket 7** processors.

e-services

E-services, a business concept developed by Hewlett Packard (**HP**), is the idea that the World Wide Web is moving beyond **e-business** and **e-commerce** (that is, completing sales on the Web) into a new phase where many business services can be provided for a business or consumer using the Web. Some e-services, such as remote bulk printing, may be done at a Web site; other e-services, such as news updates to subscribers, may be sent to your computer. Other e-services will be done in the background without the customer's immediate knowledge. HP defines e-services as "modular, nimble, electronic services that perform work, achieve tasks, or complete transactions."

Using HP's e-services concept, any application program or information resource is a potential e-service and Internet service providers (**ISPs**) and other companies are logical distributors or access points for such services. The e-services concept also sees services being built into "cars, networked devices, and virtually anything that has a microchip in it." HP's vision is that IT departments will increasingly address their needs in a modular way so that individual modules can potentially be addressed by some e-service.

HP notes three trends:

1. The increasing availability of "**apps-on-tap**"—for accounting, payment systems, purchasing, and enterprise resource planning (**ERP**). (HP offers several of these services.)
2. An increase in the number of specialized Web **portal** sites such as OpenSkies (travel services) and Ariba.com's **e-procurement** services.
3. More **on-the-fly** handling of service requests that may require handling by several companies.

HP sees its **e-speak** application development facilities as supporting e-services. Also see **application service provider** (**ASP**).

e-signature

See "digital signature"

e-signature bill

See "Electronic Signatures in Global and National Commerce Act"

ESMR

Also see Specialized Mobile Radio (**SMR**).

ESMR (Enhanced Specialized Mobile Radio) is a **wireless** communication system in which numerous mobile/portable transceivers are linked in a network of repeaters. Each **repeater** has a range of approximately 5 to 10 miles. Operating frequencies are in the UHF (ultra-high-frequency) range, that is, between approximately 300 **MHz** and 3 **GHz**. Usually, the working band is near 900 MHz.

ESMR can function like its fundamentally simpler cousin, SMR, but it can also offer features similar to those of a **cellular telephone** network. The PTT (push-to-talk), **half-duplex** mode can be used; in this case the operation resembles communications between old style two-way radios. **Full-duplex** mode can also be used, so either party can listen and talk at the same time. Interconnection with the telephone networks is commonly done. In addition to voice communication, an ESMR system can offer paging, wireless fax, and data transmission.

ESMR systems use digital radio transmission. **Spread-spectrum** modes, such as frequency hopping, are common. In a well-designed ESMR system, connection is almost instantaneous, compared with the typical 15 to 20 seconds required to dial and set up a call in a public cellular network. The coverage of an ESMR system depends on the geographical distribution and needs of the users. Some systems are confined to single municipalities; others cover selected groups of metro areas; others operate over entire states or regions of a country.

Examples of ESMR networks include Ericsson's EDACS (Enhanced Digital Access Communications System), Motorola's IDEN (Integrated Dispatch Enhanced Network), and the Nextel System.

ESMTP

ESMTP, an abbreviation for Extended Simple Mail Transfer Protocol, specifies extensions to the original protocol for sending e-mail that supports graphics, audio and video files, and text in various national languages. The original Internet protocols for sending e-mail are described in Request for Comments RFC 822, Standard for the Format of ARPA Internet Text Messages, and in RFC 821, Simple Mail Transfer Protocol. As users began to want to attach various kinds of files to e-mail, the need for additional capabilities arose and resulted in RFC 1869, Extended Simple Mail Transfer Protocol.

ESMTP provides the capability for a **client** e-mail program to inquire of a **server** e-mail program about which capabilities it supports and then communicate accordingly. Currently, most commercial e-mail servers and clients support ESMTP.

e-speak

E-speak is an open software platform designed by HP to facilitate the delivery of e-services (electronic services) over the Internet. Based on Extensible Markup Language (XML) and often compared to Microsoft's .Net initiative, e-speak was designed to automate tasks people would have to complete personally by letting the computers involved talk to each other.

To understand e-speak, pretend you are thinking of taking a vacation to Paris. Instead of searching the Web for an airline, hotel, and rental car (and then spending hours

looking through individual Web sites to see which services/ prices fit your criteria), you would submit your criteria to a registered e-services site and a services **agent** would find the registered providers that met your requirements. An added advantage of using a registered e-service site would be that if for some reason you missed your flight and had to take a later one, all the e-services site computers involved in your travel arrangements would notify each other and re-adjust your reservations accordingly.

Although HP has given up propriety rights to e-speak, it plans to sell servers, storage, and application solutions to developers who plan to use e-speak on their Web sites. HP is also using e-speak for its own product management.

e-tailing

E-tailing (less frequently: *etailing*) is the selling of retail goods on the Internet. Short for "electronic retailing," and used in Internet discussions as early as 1995, the term seems an almost inevitable addition to **e-mail**, **e-business**, and **e-commerce**. E-tailing is synonymous with business-to-consumer (B2C) transaction.

E-tailing began to work for some major corporations and smaller entrepreneurs as early as 1997 when Dell Computer reported multimillion dollar orders taken at its Web site. The success of Amazon.com hastened the arrival of Barnes and Noble's e-tail site. Concerns about secure order-taking receded. 1997 was also the year in which Auto-by-Tel reported that they had sold their millionth car over the Web, and CommerceNet/Nielsen Media reported that 10 million people had made purchases on the Web. Jupiter research predicted that e-tailing would grow to \$37 billion by 2002.

E-tailing has resulted in the development of **e-tailware**—software tools for creating online catalogs and managing the business connected with doing e-tailing. A new trend is the price comparison site that can quickly compare prices from a number of different e-tailers and link you to them.

e-tailware

E-tailware is software for creating online catalogs, ordering forms, credit checking, and similar services for Web sites that sell goods and services to consumers. A number of e-tailware products provide a complete range of support so that a company that already has a Web site can easily add e-tailing capability to the site.

EtherExpress

EtherExpress is a technology from Intel that is used in network server adapters (devices that attach the **server** to the network cable) for **Ethernet**-based local area networks (LANs). The EtherExpress adapter has a built-in i960 **processor** (an Intel processor with 32-bit RISC-based architecture) that allows it to offload work from the server's

processor, improving network efficiency by reducing demands on server resources. Adapters that offload processor work are known as *intelligent* adapters.

Network adapter performance is usually assessed by comparing its data **throughput** (the rate at which data can be sent and received, measured in megabits per second or in frames per second) against the **host** CPU utilization, a measurement of the proportion of time the server's processor has to spend on network-related tasks. EtherExpress technology enhances adapter performance both by increasing throughput and by lowering CPU utilization, which increases the amount of time the server has for other requests.

EtherExpress server adapters are designed to take advantage of a number of advanced server technologies, such as:

- **Adapter Fault Tolerance (AFT)**, a method of protecting vital network links through the use of multiple adapters and redundant links which take over automatically if the first link fails
- **Adaptive Load Balancing (ALB)**, which allows as many as four adapters to handle outgoing server traffic, enabling scalable network bandwidth increases (up to 400 Mbps)
- **Fast EtherChannel (FEC)**, a technology from Cisco Systems that balances incoming and outgoing traffic to increase throughput
- **PCI Hot Plug**, a technology from Compaq that makes it possible for a failed adapter to be hot swapped (replaced without powering down the server), allowing the network to function normally throughout the procedure.

EtherExpress server adapters include the EtherExpress PRO/100+ Server Adapter, the EtherExpress PRO/100 Intelligent Server Adapter, and the EtherExpress PRO/1000 Gigabit Server Adapter.

Ethernet

Ethernet is the most widely-installed **local area network** (LAN) technology. Specified in a standard, IEEE 802.3, Ethernet was originally developed by Xerox and then developed further by Xerox, DEC, and Intel. An Ethernet LAN typically uses **coaxial cable** or special grades of **twisted pair** wires. The most commonly installed Ethernet systems are called **10BASE-T** and provide transmission speeds up to 10 Mbps. Devices are connected to the cable and compete for access using a Carrier Sense Multiple Access with Collision Detection (**CSMA/CD**) protocol.

Fast Ethernet or 100BASE-T provides transmission speeds up to 100 megabits per second and is typically used for LAN **backbone** systems, supporting workstations with 10BASE-T cards. **Gigabit Ethernet** provides an even higher level of backbone support at 1000 megabits per second (1 gigabit or 1 billion bits per second).

ETL

See "extract, transform, load"

ETRN

ETRN (Extended Turn) is an extension to the Simple Mail Transfer Protocol (**SMTP**) that allows an SMTP **server** to send a request to another SMTP server to send any e-mail messages it has. Typically, SMTP is used with two other **protocols**, Post Office Protocol 3 (**POP3**) and Internet Message Access Protocol (**IMAP**), to request messages from a server because SMTP by itself cannot request mail to be sent.

ETRN is designed for use by anyone who is traveling and wants to get access to their mail. ETRN can only be used with Internet service providers that support ETRN. The latest version of the widely used SMTP server, **sendmail**, supports ETRN. The details of ETRN are in **Request for Comments** 1985 of the Internet Engineering Task Force (**IETF**), *SMTP Service Extension for Remote Message Queue Starting*.

ETSI

The European Telecommunications Standards Institute (ETSI) is a non-profit organization that establishes telecommunications standards for Europe. ETSI guidelines are voluntary and almost always comply with standards produced by international bodies.

ETSI initiatives touch on the following areas: aeronautical radio, API, ATM, electromagnetic compatibility, electronic signature, Generic Addressing and Transport protocol, maritime radio, service provider access, Telecommunications Management Network (TMN), **TETRA**, **VoIP**, and **xDSL**.

ETSI's structure includes a general assembly, a board, a technical organization, and a secretariat. Its technical organization has primary responsibility for devising standards.

ETSI is headquartered in southern France. It currently has 789 members from 52 countries and five continents. Its membership list features some of the biggest names in technology, including IBM Europe, Microsoft Europe, Hewlett-Packard France, Motorola, and Lucent Technologies. Membership is open to any firm with an interest in European telecommunications. Each member pays an annual fee to join ETSI.

EULA

See "End User License Agreement"

euro

The euro (pronounced YUR-oh) is now the official monetary unit of 11 member nations of the European Union. Having a common monetary unit is expected to make trade more efficient, make price comparisons easier, and stabilize interest rates overall. The euro is being phased in over a three-year period that began on January 1, 1999. Initially, the euro will be “bank money” only. Travellers can charge their credit cards in either euros or the local currency. Banks will need to be able to accept euros and convert them into their local money. Coin and note euros will not be available until 2002. (The coins have been designed, however, and candy makers are stamping them out in chocolate.)

Countries That Are Using the Euro

Austria, Belgium, Finland, France, Germany, Ireland, Italy, Luxembourg, the Netherlands, Portugal, and Spain are European Union member nations that have accepted the euro as their official currency. For the next three years, each country will use both the euro and the existing local currency. (For cash purchases, only the local currency will be available until 2002. For credit card charges, either the euro or the local currency can be used.)

Countries That Are Not Using the Euro

Britain, Denmark, Greece, and Sweden are not using the euro. Britain, Denmark, and Sweden may decide to join later. Greece did not meet the economic requirements.

What the Euro Means to Most of Us

If you trade or travel in Europe, you will be able to charge purchases in euros, using most major credit cards, including Visa International, the most popular credit card. American Express is printing travelers checks denominated in euros. Change will be returned in local currency. Since many prices will now be quoted in euros as well as in the local currency, you can easily compare prices for the same goods and services in different countries. Over time, this is expected to make prices more consistent among the countries that use the euro. For the time being, however, travellers can continue to deal entirely with local currencies.

Bank customers can have accounts in either euros or national currencies.

What the Euro Means to Large Businesses

Since many computer business applications involve accounting or sums of money that may now accept euros, these programs will need to be updated. The cost to business will be considerable, perhaps a third of the cost of the 2000 problem. In the beginning, businesses will tend to phase in the acceptance of or preference for euros over national currencies.

In terms of trading, the euro is expected to help stabilize the European economy as a whole. The 11 countries using the euro represent 290 million people.

What the Euro Means to the Financial Markets

European financial markets now quote stocks, bonds, and mutual funds in euros. Public debts are also expressed in euros.

Exchange Rates

Euros are now the only currency traded against other world currencies, such as the dollar and the Japanese yen. Exchange trading in German marks, French francs, and so forth no longer exists. Many stock market and finance Web sites post the latest exchange rates.

European Computer Driving License

The European Computer Driving License (ECDL) is a certification for qualified computer operators in the same way that a regular driving license is a certification for qualified vehicle operators—although it differs in that one may lawfully operate a computer without a computer driving license.

The ECDL Foundation, which was set up by the Council of European Professional Informatics Societies (CEPIS), developed the certification program as a way of to promote information technology skills among the general population and skill standardization within the IT industry. The ECDL Foundation developed from an earlier CEPIS group, the User Skills Task Force, and was established in Dublin in January 1997 as a non-profit organization.

The ECDLF syllabus claims: “A European Computer Driving Licence always certifies the same standard of competence, irrespective of a person’s nationality, residence, education, age or sex.” The original ECDLF members agreed on the standards to be met by license holders when the project began; subsequently the foundation issued a revised “Standards and Guidelines” report in March of 1998.

To obtain ECDL certification, an individual must pass a test about basic IT knowledge as well as six practice-based tests of competence using a computer and popular computer **applications**. Employers frequently require employees—or potential employees—to attain ECDL certification.

ECDLF has branches in most European countries; it also has a number of members internationally through its International Computer Driving License (ICDL) Foundation.

EUTELSAT

EUTELSAT (European Telecommunications Satellite Organization) refers to both the organization and its set of **satellites** that were placed in geostationary orbits over Europe beginning in 1983. By early 1998, at least 48 countries had become members of EUTELSAT and the satellites were serving both public and private traffic, including telephone services, fax, data, land mobile service, and television and radio programming to home and business users with their own receivers. Since its first satellites, EUTELSAT has launched a succession of more capable and powerful spacecraft. Recently, EUTELSAT has begun offering Internet services including Web page transmission via digital television, using the MPEG-2 DVB (Moving Picture Experts Group Direct Video Broadcasting) standard, a new European standard for digital television. Users are Internet service providers and cable companies that can redistribute Internet files via ground lines as well as private users with PC cards and set-top boxes.

EUVL

See "extreme ultraviolet lithography"

evergreen

On the Internet, *evergreen* is a term used by some ad agencies to describe a **Web site** that is updated on a daily or other frequent basis. A Web site that is evergreen is considered more likely to attract both first-time and repeat visitors. If a media buyer for an ad agency is selecting a number of sites for an ad campaign, whether a site is considered evergreen may determine whether it's included in the campaign. A Web site that is not updated frequently enough is termed *brown*.

Web sites or tools (such as Alexa) that evaluate other sites sometimes rate a site for *freshness*. One obvious way to change a site every day is to include **JavaScript** code on the home page that automatically changes the date. This is not usually enough to warrant a rating of "evergreen," however.

Evernet

The term *Evernet* has been used to describe the convergence of **wireless**, **broadband**, and **Internet telephony** technologies that will result in the ability to be continuously connected to the Web anywhere using virtually any information device. Considered the next generation of Internet access, the Evernet assumes the emergence of an amount of **bandwidth** that would enable millions of homes to access the Web through inexpensive **cable modem**, **DSL**, or wireless connections.

The "Evernet" can also be considered to include common household appliances and home and office networks that include devices that control the environment; such networks require an "always on" capability. In addition, portable devices that can connect quickly and easily without wires to other devices (see **Bluetooth**) might also be considered part of the Evernet.

e-voting

E-voting (sometimes called electronic voting, online voting, or Internet voting) is an election system that uses **encryption** to allow a voter to transmit his or her secure and secret ballot over the Internet. Critics of electronic voting express concerns about Web security and the lack of equal access to the Internet for all citizens (see **digital divide**). Advocates of e-voting cite the potential for reduced election costs, as well as the potential for increasing civic participation by making the voting process more convenient. Furthermore, they foresee that advances in **cryptography** will soon make submitting a governmental election ballot online just as common as filing an income tax return online is in the U. S.

At this time, e-voting is used primarily for conducting non-governmental elections, although a number of citizens in Switzerland and the U.S. (Arizona, parts of Alaska and California) have had the opportunity to be pioneers in the submission of governmental election ballots over the Internet, with varying degrees of success. Experts around the world agree that in governmental elections, the need to create a standardized, secure process for the verification, collection, and counting of votes must be addressed satisfactorily before online voting becomes a viable option.

There are several groups working to create online voting standards. In the U.S., the Federal Voting Assistance Program (FVAP) at the Pentagon, the California Secretary of State Internet voting task force, the NASED ITA subcommittee, and several third-party vendors are researching and testing voting models and software applications and examining standards to make online voting an option in time for the 2004 Presidential election. An international group of experts and companies, called *The Internet Voting Technology Alliance* is working on an open peer review of standards that could be used in e-voting throughout the world.

As of this writing, each of these groups has a different solution with different security standards and risks, although there are three Internet electronic voting models that each group seems to feel holds promise: automation of the current process, electronic voting at a secure Web site, and electronic voting at regional centers.

EWSD

EWSD (Electronic Worldwide Switch Digital, or, in German, Elektronisches WaehlSystem [Digital]) is a widely-installed telephonic **switch** system developed by Siemens. Siemens

says that EWSD performs switching for over 160 million lines in more than 100 countries. EWSD is a **modular** system in which some switches in the system can be installed in a telephone company's **centrex** facility and other switches can be located at the customer.

Important features of EWSD include the following:

- Advanced Intelligent Network (AIN) 0.1 and 0.2 capabilities allow switching services to be added at Service Control Points, meaning that new services can be added and performed by the switching system without the customer having to buy new equipment.
- In addition to AIN capabilities, EWSD provides **ISDN**, **CLASS**, **SS7**, and **centrex** services.
- **Digital** and **analog** lines can be combined in the same line groups, allowing full **interoperability** between digital and analog terminals.
- Carriers using EWSD can provide **Automatic Call Distributor** services for customers with **call centers**.
- EWSD provides both **Bellcore** AIN 0.2 and Global System for Mobile (**GSM**) communications for **personal communications services**.

Line types supported include single or two-party analog, coin, TR08, and ISDN **Basic Rate Interface**. Unidirectional Digital Subscriber Line (**DSL**) support is planned. Any line type can be added by simply changing the line card.

exabyte

An exabyte (EB) is a large unit of computer data storage, two to the sixtieth power **bytes**. The prefix *exa* means one billion billion, or one quintillion, which is a decimal term. Two to the sixtieth power is actually 1,152,921,504,606,846,976 bytes in decimal, or somewhat over a quintillion (or ten to the eighteenth power) bytes. It is common to say that an exabyte is approximately one quintillion bytes. In decimal terms, an exabyte is a billion **gigabytes**.

Exchange Rate Mechanism

The Exchange Rate Mechanism (ERM) is part of the European Monetary Union (EMU) that began operating in 1999.

exchange-to-exchange

See "E2E"

executable

In computers, to execute a **program** is to run the program in the computer, and, by implication, to start it to run. In usage, people run programs and systems execute them. That is, a system user asks the system to run the program (or sets it up so that this happens automatically at a certain time) and, as a result, the system executes the program. Typically, we don't say that a program is executing; we say that it is running.

A computer **processor** executes an **instruction**, meaning that it performs the operations called for by that instruction.

An executable is a **file** that contains a program—that is, a particular kind of file that is capable of being executed or run as a program in the computer. In a **Disk Operating System** or Windows operating system, an executable file usually has a file name extension of .bat, .com, or .exe. An executable file or a group of them are sometimes referred to as *binaries* as in "I'll download the binaries to you" since the file format of an executable is a solid sequence of binary values that cannot be easily read by anyone (unlike that of, for example, an ASCII text file which can be easily examined for information as it travels from one computer to another).

A file whose name ends in ".exe" is really a program that when "opened"—that is, selected by putting your mouse over the file name and then initiated by double-clicking your mouse, for example—causes the operating system to run the program. Users who receive an .exe file as an e-mail attachment should always be sure that the file comes from a trusted source and is not, in fact, a computer **virus**.

exit program

1) In computer programming, an exit program (or exit routine) is a named unit of programming code that is entered when a particular condition occurs, such as one that requires some screening for authorization. An exit program may be part of an **operating system** or part of an **application program**.

2) In the IBM **AS/400 operating system**, an exit program is a supplemental security measure that controls user access to applications, and prevents access outside of authorized applications. An AS/400 exit program (so called because the system exits to the program in the middle of a request from the user) is not used—as might be expected—to exit from a program, but to process user requests: It monitors user activity, checks to see if user requests comply with installation rules, and rejects those requests that contravene those rules.

expert system

An expert system is a computer program that simulates the judgement and behavior of a human or an organization that has expert knowledge and experience in a particular field. Typically, such a system contains a knowledge base containing accumulated experience and a set of rules for applying the knowledge base to each particular situation that is described to the program. Sophisticated expert systems can be enhanced with additions to the knowledge base or to the set of rules.

Among the best-known expert systems have been those that play chess and that assist in medical diagnosis.

explicit parallelism

Explicit parallelism is a concept of **processor-compiler** efficiency in which a group of **instructions** is sent from the compiler to the processor for simultaneous rather than sequential execution. Explicit parallelism is a feature of Explicitly Parallel Instruction Computing (**EPIC**) and Intel's EPIC-based architecture, **IA-64**.

Explicitly Parallel Instruction Computing

See "EPIC"

exploit

In computing, an exploit is an attack on a computer system, especially one that takes advantage of a particular vulnerability that the system offers to intruders. Used as a verb, the term refers to the act of successfully making such an attack.

Many **crackers** (or **hackers**, if you prefer that term) take pride in keeping tabs of such exploits and post their exploits (and discovered vulnerabilities) on a Web site to share with others.

Where an exploit takes advantage of a weakness in an **operating system** or vended **application program**, the owners of the system or application issue a "fix" or **patch** in response. Users of the system or application are responsible for obtaining the patch, which can usually be downloaded from the Web. Failure to install a patch for a given problem exposes the user to a security breach. (However, it can be difficult to keep up with all the required patches.)

exploratory model

The exploratory model is a systems development method (**SDM**) occasionally used to design and develop a computer system or product and basically consists of planning and trying different designs until one of them seems to be the right one to develop. This model works best in situations where few, or none, of the system or product requirements are known in detail ahead of time. This model is largely based on educated guesswork.

There are several steps in the exploratory model:

1. A starting point is determined for the work. All the information available is gathered together in an attempt to get an idea of what the new system will be expected to do, and how it can be done.
2. A rudimentary first-generation system is put together, based on the information gathered and the ideas formulated in the first step.
3. The first-generation system is tested to see how it performs, what it can and cannot do, and what might be done to improve it.

4. A second-generation system is developed from the first one, based on the improvements proposed in the previous step.
5. The second-generation system is tested, as was the first. Its performance is evaluated, and possible improvements determined.
6. The process is repeated as many times as necessary to obtain user satisfaction, or until it is decided that the project is unworkable.
7. Routine maintenance is carried out on a continuing basis to prevent large-scale failures and to minimize downtime.

This model resembles the prototyping model, but it begins at a more nebulous starting point, and proceeds in a less formal fashion. This scheme is not particularly cost-effective and sometimes results in less-than-optimal systems, so it should be used only when no viable alternative seems to exist.

exponential assembly

In **nanotechnology**, exponential assembly is a form of self-replication in which tiny devices called nanorobots repeatedly construct copies of themselves. Four conditions must be met for exponential assembly to take place in an orderly manner.

The first condition is that each nanorobot must construct at least two copies of itself during its operational life. These copies must be exact in every detail, including the ability to reproduce. The more copies each unit can produce, the more rapidly the population will grow.

The second condition is that there must exist sufficient energy and ingredients so the process can continue for the specified length of time, or until a specified population of nanorobots is reached. Because the population grows exponentially, the number of units will increase rapidly. For example, if a population begins with one nanorobot, and if each unit creates three copies of itself, then the population will grow by powers of three. Suppose replication takes place on a daily basis and each nanorobot ends its useful life as soon as it has reproduced. Then after two days the population will be $3^2 = 9$ units, after three days it will be $3^3 = 27$ units, after four days it will be $3^4 = 81$ units, and, in general, after n days the population will be 3^n units.

The third condition for exponential assembly is that the environment be controlled so the replication process can proceed efficiently. Excessive turbulence, temperature extremes, intense radiation, or other adverse circumstances might prevent the proper functioning of the nanorobots and cause the process to falter or fail before it is supposed to terminate.

The fourth condition is that the process be programmed to end at a certain point, or be modified so that the population cannot exceed a certain maximum number of units.

Otherwise, the nanorobots will eventually crowd each other out of their world, and the process will come to a catastrophic halt.

Compare **self-replication** and also see **nanotechnology**, **positional assembly**, and **self-assembly**.

exponential function

An exponential function is a mathematical function of the following form:

$$f(x) = a^x$$

where x is a variable, and a is a constant called the base of the function. The most commonly encountered exponential-function base is the **transcendental number** e , which is equal to approximately 2.71828. Thus, the above expression becomes:

$$f(x) = e^x$$

When the exponent in this function increases by 1, the value of the function increases by a factor of e . When the exponent decreases by 1, the value of the function decreases by this same factor (it is divided by e).

In electronics and experimental science, base-10 exponential functions are encountered. The general form is:

$$f(x) = 10^x$$

When the exponent increases by 1, the value of the base-10 function increases by a factor of 10; when the exponent decreases by 1, the value of the function becomes 1/10 as great. A change of this extent is called one order of magnitude.

For a given, constant base such as e or 10, the exponential function “undoes” the **logarithm** function, and the logarithm undoes the exponential. Thus, these functions are inverses of each other. For example, if the base is 10 and $x = 3$:

$$\log(10^3) = \log(10^3) = \log 1000 = 3$$

If the base is 10 and $x = 1000$:

$$10^{(\log x)} = 10^{(\log 1000)} = 10^3 = 1000$$

extensible

In information technology, **extensible** describes something, such as a program, programming language, or protocol, that is designed so that users (or later designers) can extend its capabilities. Extensibility can be a primary reason for the system, as in the case of the Extensible Markup Language (XML), or it may be only a minor feature.

Approaches to extensibility include facilities (sometimes called **hooks**) for allowing users to insert their own program routines, the ability to define new **data types**, and the ability to define new formatting **markup tags**.

extension

1) In computer operating systems, a **file** name extension is an optional addition to the file name in a **suffix** of the form “.xxx” where “xxx” represents a limited number of alphanumeric characters depending on the operating system. (In Windows 3.1, for example, a file name extension or suffix can have no more than three characters, but in Windows 95 and later, it can have more.) The file name extension allows a file’s format to be described as part of its name so that users can quickly understand the type of file it is without having to “open” or try to use it. The file name extension also helps an application program recognize whether a file is a type that it can work with.

2) In programming, an extension is a file containing programming that serves to extend the capabilities of or data available to a more basic program. Extensions are sometimes required to be stored in a separate extensions file so that

they're easy to locate. When installing software, you may be instructed to take one or more steps related to installing extensions (or these steps may automatically be done for you).

Exterior Gateway Protocol

Exterior Gateway Protocol (EGP) is a **protocol** for exchanging routing information between two neighbor **gateway hosts** (each with its own **router**) in a network of autonomous systems. EGP is commonly used between hosts on the Internet to exchange routing table information. The routing table contains a list of known routers, the addresses they can reach, and a cost **metric** associated with the path to each router so that the best available route is chosen. Each router polls its neighbor at intervals between 120 to 480 seconds and the neighbor responds by sending its complete routing table. EGP-2 is the latest version of EGP.

A more recent exterior gateway protocol, the Border Gateway Protocol (**BGP**), provides additional capabilities.

Also see Interior Gateway Protocol (**IGP**).

external storage

External storage is all addressable data **storage** that is not currently in the computer's **main storage** or **memory**. Synonyms are **auxiliary storage** and **secondary storage**.

extract, transform, load

In managing databases, extract, transform, load (ETL) refers to three separate functions combined into a single programming tool. First, the extract function reads data from a specified source **database** and extracts a desired subset of data. Next, the transform function works with the acquired data—using rules or lookup tables, or creating combinations with other data—to convert it to the desired state. Finally, the load function is used to write the resulting data (either all of the subset or just the changes) to a target database, which may or may not previously exist.

ETL can be used to acquire a temporary subset of data for reports or other purposes, or a more permanent data set may be acquired for other purposes such as: the population of a **data mart** or **data warehouse**; conversion from one database type to another; and the migration of data from one database or platform to another.

extranet

An extranet is a private network that uses the Internet **protocol** and the public telecommunication system to securely share part of a business's information or operations with suppliers, vendors, partners, customers, or other businesses. An extranet can be viewed as part of a company's **intranet** that is extended to users outside the

company. It has also been described as a "state of mind" in which the Internet is perceived as a way to do business with other companies as well as to sell products to customers.

An extranet requires security and privacy. These require **firewall** server management, the issuance and use of **digital certificates** or similar means of user authentication, **encryption** of messages, and the use of virtual private networks (**VPN**) that tunnel through the public network.

Companies can use an extranet to:

- Exchange large volumes of data using Electronic Data Interchange (**EDI**)
- Share product catalogs exclusively with wholesalers or those "in the trade"
- Collaborate with other companies on joint development efforts
- Jointly develop and use training programs with other companies
- Provide or access services provided by one company to a group of other companies, such as an online banking application managed by one company on behalf of affiliated banks
- Share news of common interest exclusively with partner companies

Netscape, Oracle, and Sun Microsystems have announced an alliance to ensure that their extranet products can work together by standardizing on **JavaScript** and the Common Object Request Broker Architecture (**CORBA**). Microsoft supports the Point-to-Point Tunneling Protocol (**PPTP**) and is working with American Express and other companies on an Open Buying on the Internet (OBI) standard. The Lotus Corporation is promoting its groupware product, **Notes**, as well-suited for extranet use.

extrapolation and interpolation

Extrapolation is an estimation of a value based on extending a known sequence of values or facts beyond the area that is certainly known.

Interpolation is an estimation of a value within two known values in a sequence of values.

Extreme Programming

Extreme Programming (XP) is a pragmatic approach to program development that emphasizes business results first and takes an incremental, get-something-started approach to building the product, using continual testing and revision. The conception of Kent Beck, who has written a book about it, XP proceeds with the view that code comes first. Beck emphasizes that in order to write the code, however, you have to write a test for it first so that you will know when your code succeeds. Beck also introduces the relatively novel

idea that code should be written by pairs of programmers, forcing the main programmer to describe the code to the other programmer and perhaps to stimulate further ideas.

Beck calls Extreme Programming a “lightweight methodology” that challenges the assumption that getting the software right the first time is the most economical approach in the long run. Beck’s fundamental idea is to start simply, build something real that works in its limited way, and then fit it into a design structure that is built as a convenience for further code building rather than as an ultimate and exhaustive structure after thorough and time-consuming analysis. Rather than specialize, all team members write code, test, analyze, design, and continually integrate code as the project develops. Because there is much face-to-face communication, the need for documentation is minimized, according to Beck.

extreme ultraviolet lithography

Extreme ultraviolet lithography (EUVL) is an advanced technology for making microprocessors a hundred times more powerful than those made today. Intel, AMD, and Motorola have joined with the U.S. Department of Energy in a three-year venture to develop a microchip with etched circuit lines smaller than 0.1 **micron** in width. (Today’s circuits are generally .18 micron or greater.) A **microprocessor** made with the EUVL technology would be a hundred times more powerful than today’s. **Memory** chips would be able to store 1,000 times more information than they can today. The aim is to have a commercial manufacturing process ready before 2005.

EUVL is one technology vying to replace the optical lithography used to make today’s microcircuits. It works by burning intense beams of ultraviolet light that are reflected from a circuit design pattern into a **silicon** wafer. EUVL is similar to optical lithography in which light is refracted through camera lenses onto the wafer. However, extreme ultraviolet light, operating at a different **wavelength**, has different properties and must be reflected from mirrors rather than refracted through lenses. The challenge is to build mirrors perfect enough to reflect the light with sufficient precision. Intel is working on some early prototypes. In the meantime, optical lithography will continue to advance over the next few years until replaced by newer technologies such as EUVL.

extremely low frequency

See “ELF”

eye candy

Eye candy is a term used in information technology for visual elements displayed on computer monitors that are aesthetically appealing or attention-compelling. There are several different usages:

- 1) Eye candy sometimes means any frill or decorative design intended to enhance the basic content of a presentation. In this usage, the connotation of “unnecessary” may or may not be present.
- 2) It is also used to refer to software that produces psychedelic or **fractal** images on a display as a screensaver or background. Some eye candy programs use audio input to generate sympathetic graphical output—in effect, sophisticated sound-to-light effects. In some cases, the software exists solely to provide visual entertainment or atmosphere as either a background or as a celebration of the technological possibilities.

eye-in-hand system

An eye-in-hand system is a **robot end effector** equipped with a close-range camera. The camera is designed for work at distances from a fraction of a millimeter to approximately one meter. A lamp is included in the gripper (robot hand) along with the camera to ensure that a good image is obtained in dim light. The camera has a lens that can be adjusted for proper focus, so the positioning error is minimized.

Eye-in-hand systems are used primarily to guide robot end effectors and grippers, and to ensure that grippers properly engage the intended targets. The system can also precisely measure the distance from the end effector or gripper to a target. In a robot equipped with a smart controller, the eye-in-hand system allows positive identification of a target. The controller compares the image from the camera with a set of images stored in memory.

Also see **motion plan** and **robotics**.

ezine

The term *ezine* is short for “electronic magazine.” “E-zine” and “e-Zine” are spelling variations. A similar term is “ejournal.” There are several usages of the term *ezine*. The term is similar to *zine*, which is derived from *magazine* and is used to describe “small press” or personally distributed magazines or newsletters.

- 1) An early use of the term *ezine* described a new kind of Web site that contained a stylized mixture of content (articles, pictures, poetry, fiction, and comment) conveyed in a way that exploited and celebrated the Web as a new information medium. Examples include Salon and HotWired.

2) Some ezines publishers saw ezines as an opportunity to reach an audience electronically and more economically than was possible with print medium. As a result, hundreds of Web site ezines were created, each devoted to a special cause, subject, or sensibility. This kind of ezine is roughly the cyberspace equivalent of the printed version and when printed out, is in fact, the equivalent.

3) The term is also used to describe any print magazine such as *National Geographic* or *Newsweek* that also has an electronic edition.

4) The term also sometimes includes e-mail newsletters, of which there are thousands that can be subscribed to. Some of these refer to themselves as zines or ezines.

failover

Failover is a backup operational mode in which the functions of a system component (such as a **processor**, **server**, network, or database, for example) are assumed by secondary system components when the primary component becomes unavailable through either failure or scheduled down time. Used to make systems more **fault-tolerant**, failover is typically an integral part of **mission-critical** systems that must be constantly available. The procedure involves automatically offloading tasks to a standby system component so that the procedure is as **seamless** as possible to the end user. Failover can apply to any aspect of a system: Within a personal computer, for example, failover might be a mechanism to protect against a failed processor; within a network, failover can apply to any network component or system of components, such as a connection **path**, storage device, or Web server.

Originally, stored data was connected to servers in very basic configurations: either point-to-point or cross-coupled. In such an environment, the failure (or even maintenance) of a single server frequently made data access impossible for a large number of users until the server was back online. More recent developments, such as the storage area network (SAN), make any-to-any connectivity possible among servers and data storage systems. In general, storage networks use many paths—each consisting of complete sets of all the components involved—between the server and the system. A failed path can result from the failure of any individual component of a path. Multiple connection paths, each with **redundant** components, are used to help ensure that the connection is still viable even if one (or more) paths fail. The capacity for automatic failover means that normal functions can be maintained despite the inevitable interruptions caused by problems with equipment.

Fair Information Practices

FIP (Fair Information Practices) is a general term for a set of standards governing the collection and use of personal data and addressing issues of privacy and accuracy. Different organizations and countries have their own terms for these concerns—the UK terms it “Data Protection,” the European Union calls it “Personal Data Privacy,” and the OECD has written *Guidelines on the Protection of Privacy and Transborder Flows of Personal Data*, which states these principles:

Collection Limitation Principle: There should be limits to the collection of personal data and any such data should be obtained by lawful and fair means and, where appropriate, with the knowledge or consent of the data subject.

Data Quality Principle: Personal data should be relevant to the purposes for which they are to be used, and, to the extent necessary for those purposes, should be accurate, complete and kept up-to-date.

Purpose Specification Principle: The purposes for which personal data are collected should be specified not later than at the time of data collection and the subsequent use limited to the fulfillment of those purposes or such others as are not incompatible with those purposes and as are specified on each occasion of change of purpose.

Use Limitation Principle: Personal data should not be disclosed made available or otherwise used for purposes other than those specified in accordance with the Purpose Specification Principle except:

- a) with the consent of the data subject; or
- b) by the authority of law.

Security Safeguards Principle: Personal data should be protected by reasonable security safeguards against such risks as loss or unauthorized access, destruction, use, modification or disclosure of data.

Openness Principle: There should be a general policy of openness about developments, practices and policies with respect to personal data. Means should be readily available of establishing the existence and nature of personal data, and the main purposes of their use, as well as the identity and usual residence of the data controller.

Individual Participation Principle: An individual should have the right:

- a) to obtain from a data controller, or otherwise, confirmation of whether or not the data controller has data relating to him;
- b) to have communicated to him, data relating to him within a reasonable time; at a charge, if any, that is not excessive; in a reasonable manner; and in a form that is readily intelligible to him;
- c) to be given reasons if a request made under subparagraphs (a) and (b) is denied, and to be able to challenge such denial; and
- d) to challenge data relating to him and, if the challenge is successful to have the data erased, rectified, completed or amended.

Accountability Principle: A data controller should be accountable for complying with measures which give effect to the principles stated above.

#

These principles are reprinted from <http://www.junkbusters.com/ht/en/fip.html#OECD> under the terms of the GNU General Public License.

FAQ

See "frequently-asked questions"

farad

The farad (symbolized F) is the standard unit of **capacitance** in the International System of Units (SI). Reduced to base SI units, one farad is the equivalent of one second to the fourth power **ampere** squared per kilogram per meter squared ($s^4 \cdot A^2 \cdot kg^{-1} \cdot m^{-2}$).

When the **voltage** across a 1 F capacitor changes at a rate of one **volt** per second (1 V/s), a **current** flow of 1 A results. A capacitance of 1 F produces 1 V of potential difference for an electric charge of one **coulomb** (1 C). The farad is an extremely large unit of capacitance. In practice, capacitors with values this large are almost never seen.

In common electrical and electronic circuits, units of microfarads (μF), where $1 \mu F = 10^{-6} F$, and picofarads (pF), where $1 pF = 10^{-12} F$, are used. At radio frequencies (**RF**), capacitances range from about 1 pF to 1,000 pF in tuned circuits, and from about 0.001 μF to 0.1 μF for blocking and bypassing. At audio frequencies (**AF**), capacitances range from about 0.1 μF to 100 μF . In power-supply filters, capacitances can be as high as 10,000 μF .

Also see **capacitor**, **inductor**, **reactance**, and **henry**.

fast retransmit and recovery

In **TCP/IP**, fast retransmit and recovery (FRR) is a congestion control **algorithm** that makes it possible to quickly recover lost data packets. Without FRR, the TCP uses a timer that requires a retransmission timeout if a packet is lost. No new or duplicate **packets** can be sent during the timeout period. With FRR, if a receiver receives a data segment that is out of order, it immediately sends a duplicate acknowledgement to the sender. If the sender receives three duplicate acknowledgements, it assumes that the data segment indicated by the acknowledgements is lost and immediately retransmits the lost segment. With FRR, time is not lost waiting for a timeout in order for retransmission to begin.

FRR works most efficiently when there are isolated packet losses. It does not work efficiently when there are multiple data packet losses occurring over a short period of time. The fast retransmit/fast recovery algorithm was introduced in 4.3BSD Reno release and is described in RFC 2001 and RFC 2581.

Fast Ethernet

Fast Ethernet is a local area network (**LAN**) transmission standard that provides a data rate of 100 megabits per second (referred to as "100BASE-T"). Workstations with existing 10 megabit per second (10BASE-T) **Ethernet card** can be connected to a Fast Ethernet network. (The 100 megabits per second is a shared data rate; input to each workstation is constrained by the 10 Mbps card.)

fast packet technology

In data transmission, a fast **packet** is one that is transmitted without any error checking at points along the route. Assurance that the packet arrived without error is the responsibility of the receiver. Fast packet transmission is possible because of the extremely low incidence of error or data loss on **fiber optic** media and is a characteristic of high bandwidth transmission technologies such as **ATM**.

Fast Page Mode DRAM

See "FPM DRAM"

FastCGI

FastCGI is a programming interface that can speed up Web applications that use the most popular way to have the Web **server** call an application, the common gateway interface (CGI). According to one FastCGI implementor, user requests coming to a Web site and using a specific application program can be handled 3 to 30 times faster using FastCGI. FastCGI is a **plug-in** to the Web server. It requires only small changes to existing server applications (such as **Perl** or **Tcl** scripts and C and C++ programs) to get the performance benefits.

Basically, FastCGI is a program that manages multiple CGI requests within a single **process**, saving many program instructions for each request. Without FastCGI, each instance of a user requesting a service causes the Web server to open a new process that gets control, performs the service, and then is closed. With FastCGI, the overhead for one process is shared among all currently processing requests. Unlike CGI, with FastCGI, a process runs independently of the Web server, isolating it and thus providing more security. FastCGI is language-independent. It was developed and is copyrighted by Open Market, Inc., which makes it freely available and offers it as an **open** standard. It offers a single non-proprietary approach for use across platforms and on any Web server.

FAT

See "file allocation table"

fat Mac

A fat Mac application is an application program for the **Macintosh** computer that is compiled to run on either a Mac containing the Motorola 68000 series microprocessor or the **PowerPC** microprocessor. The 68000 series is the traditional Macintosh microprocessor. The more recent and faster PowerPC microprocessor was developed by Apple, IBM, and Motorola to rival or exceed the Intel microprocessor series used in PCs. A fat Mac library is one that contains library routines (program code) that will run with either microprocessor.

fatal exception

In a computer error message, a fatal exception indicates an exceptional situation requiring that the program responsible for the situation be closed. In general, an *exception* is any unanticipated situation (which includes but is not limited to program errors). A fatal exception simply means the exception can't really be handled so that the program can continue to run.

Software applications communicate with the operating system and other applications through several different layers of code. When an exception occurs at a certain layer of code, each layer sends the exception to the next layer in order to locate any exception handling code that can deal with the specific exception. If no exception handling code exists (at any layer) to deal with the exception, a fatal exception error message is generated by the operating system. This message can also contain some cryptic information about where the fatal exception error occurred (such as the hexadecimal location within the program's range of memory). This extra information has little value to the user, but may help support people or developers in debugging an application.

When a fatal exception occurs, the operating system has no other recourse but to shut down the application, and in some cases, its own operating system. When using a specific application, if you continue to experience fatal exception errors, report the problem to the software vendor.

fault-tolerant

Fault-tolerant describes a computer system or component designed so that, in the event that a component fails, a backup component or procedure can immediately take its place with no loss of service. Fault tolerance can be provided with software, or embedded in hardware, or provided by some combination. Leading vendors that specialize in fault-tolerant systems include Compaq Non-Stop (formerly Tandem), Marathon Technologies, and Stratus Computer.

In the software implementation, the **operating system** (for example, Tandem Guardian) provides an interface that allows a programmer to "checkpoint" critical data at pre-determined points within a transaction. In the hardware

implementation (for example, with Stratus and its VOS operating system), the programmer does not need to be aware of the fault-tolerant capabilities of the machine.

At a hardware level, fault tolerance is achieved by duplexing each hardware component. Disks are mirrored. Multiple **processors** are "lock-stepped" together and their outputs are compared for correctness. When an anomaly occurs, the faulty component is determined and taken out of service, but the machine continues to function as normal.

fax

Sometimes called "telecopying," a fax is the telephonic transmission of scanned-in printed material (text or images), usually to a telephone number associated with a printer or other output device. The original document is scanned with a fax machine, which treats the contents (text or images) as a single fixed graphic image, converting it into a **bitmap**. In this digital form, the information is transmitted as electrical signals through the telephone system. The receiving fax machine reconverts the coded image and prints a paper copy of the document.

Almost all **modems** manufactured today are capable of sending and receiving fax data. Fax/modem software generates fax signals directly from disk files or the screen. Even if a document is text only, it is treated by the computer as a scanned image and is transmitted to the receiver as a bitmap. Faxing a message online works well if the recipient wants only to read the message. However, if the document requires editing, it must be converted into **ASCII** text by an OCR (optical character recognition) program, or it must be retyped manually into the computer. A more efficient method of sending documents that require modification is through the e-mail system. E-mail files are already ASCII text so they can be edited immediately in any text editor or word processing program.

The Internet now provides a new and cheaper way to send faxes in some cases. A number of free and commercial companies provide arrangements for using the Internet rather than the public telephone system for most or part of the path to the fax point. Some services also provide the ability to broadcast a fax to multiple addresses.

FC/IP

See "Fibre Channel over IP"

FCAPS

FCAPS (fault-management, configuration, accounting, performance, and security) is an acronym for a categorical model of the working objectives of **network management**. There are five levels, called the fault-management level (F), the configuration level (C), the accounting level (A), the performance level (P), and the security level (S).

#

O

P

Q

R

S

T

U

V,W

X,Y,Z

At the F level, network problems are found and corrected. Potential future problems are identified, and steps are taken to prevent them from occurring or recurring. In this way, the network is kept operational, and downtime is minimized.

At the C level, network operation is monitored and controlled. Hardware and programming changes, including the addition of new equipment and programs, modification of existing systems, and removal of obsolete systems and programs, are coordinated. An inventory of equipment and programs is kept and updated regularly.

The A level, which might also be called the allocation level, is devoted to distributing resources optimally and fairly among network subscribers. This makes the most effective use of the systems available, minimizing the cost of operation. This level is also responsible for ensuring that users are billed appropriately.

The P level is involved with managing the overall performance of the network. **Throughput** is maximized, **bottlenecks** are avoided, and potential problems are identified. A major part of the effort is to identify which improvements will yield the greatest overall performance enhancement.

At the S level, the network is protected against **hackers**, unauthorized users, and physical or electronic sabotage. Confidentiality of user information is maintained where necessary or warranted. The security systems also allow network administrators to control what each individual authorized user can (and cannot) do with the system.

Fcc

In Eudora and perhaps other e-mail facilities, you'll see the abbreviations "Fcc" and "Bcc." "Fcc" is the same as "cc" or **carbon copy**—that is, send a copy of the message to the address you fill in. "Bcc" stands for "Blind carbon copy" which says: Send a copy to another address...but in this case, don't indicate to the Fcc recipient that you also sent this copy.

FC-PGA

FC-PGA (flip chip-pin grid array) is a **microchip** design developed by Intel for its faster **microprocessors** in which the hottest part of the chip is located on the side that is away from the **motherboard**.

According to Intel, the FC-PGA chip design is better than previous designs for several reasons:

- It protects the delicate circuitry of its microprocessor by making it easier to insert and remove the microprocessor within a computer. This is accomplished by way of its pin grid array construction, described below.
- It allows the microprocessor to operate more easily at its optimal temperatures by designing the processor core on the "flip side" (or backside) of the chip, facing away

from the motherboard. (The processor core, or **silicon** core, contains the delicate microprocessor engine that controls all of its actions.)

- Due to its flip-chip design, an FC-PGA microprocessor requires fewer hardware components (such as a thermal plate or heat spreader) than other chips in order to dissipate heat from the core and maintain its optimal temperature. In place of these components, an FC-PGA microprocessor allows a heatsink or other thermal device to be attached directly to the back of the processor, where the core resides. In general, PGA (pin grid array) chip packages (or PGA form factors, as they are also called), have 370 **pins** "arrayed" in a series of square "grids" at the bottom of the microprocessor. This square-pin design allows a computer hardware technician to smoothly plug the microprocessor into a PGA370 socket on a computer's motherboard, using little-to-no force. PGA370 sockets are designed with a Zero Insertion Force (**ZIF**) feature that helps the PGA chip to slide easily in and out of its socket.

Currently, two types of PGA chip packages exist for Intel Celeron and Pentium III processors: **PPGA** (plastic pin grid array) and FC-PGA (flip chip-pin grid array). PPGA chip packages are designed with the processor core facing down toward the motherboard, whereas FC-PGA packages have the processor core flipped up on the back of the chip, facing away from the motherboard. Each PGA package requires different thermal designs and components in order to keep the chips cool.

Incidentally, in order to use either type of PGA microprocessor with its associated PGA370 socket, a computer's motherboard must support certain guidelines, known as VRM specifications. (For PPGA processors, the motherboard must support VRM 8.2 specifications. For FC-PGA processors, the motherboard must support VRM 8.4 specifications.)

FDDI

FDDI (Fiber Distributed Data Interface) is a standard for data transmission on **fiber optic** lines in a local area network (**LAN**) that can extend in range up to 200 km (124 miles). The FDDI protocol is based on the **token ring** protocol. In addition to being large geographically, an FDDI local area network can support thousands of users.

An FDDI network contains two token rings, one for possible backup in case the primary ring fails. The primary ring offers up to 100 **Mbps** capacity. If the secondary ring is not needed for backup, it can also carry data, extending capacity to 200 Mbps. The single ring can extend the maximum distance; a dual ring can extend 100 km (62 miles).

FDDI is a product of American National Standards Committee X3-T9 and conforms to the Open Systems Interconnection (**OSI**) model of functional layering. It can be used to interconnect LANs using other protocols. FDDI-II is

a version of FDDI that adds the capability to add **circuit-switched** service to the network so that voice signals can also be handled. Work is underway to connect FDDI networks to the developing Synchronous Optical Network (SONET).

FDISK

WARNING: Use caution when repartitioning a hard disk drive that contains data. Repartitioning wipes out all data on the disk. Be sure to back up everything to another storage medium first.

FDISK is a **utility**, included in all versions of **MS-DOS** and Windows, for formatting (preparing) a **hard disk** drive to hold data and to logically **partition** the disk, specifying and naming major portions of it for different uses. FDISK is used to prepare and partition a brand new hard drive, and typically most personal computers today arrive with the drive already partitioned and loaded with the operating system and perhaps other software. A typical personal computer today arrives with a single partition that is addressed by the operating system as the logical C drive. (Some PCs also have one or two diskette drives addressed as the A and B drives. PCs with CD-ROMs also usually address the CD-ROM as the D drive. But a hard disk drive can be divided into and addressed as several “logical” drives, or partitions.)

In addition to setting up a new hard disk drive, FDISK is used for repartitioning the hard drive when you want to change something. For example, a computer can be set up as a **dual boot** system, with one **operating system** (for example, **Windows 2000**) in one partition and another operating system (for example, **Linux**) in another partition. Disk partitioning is also commonly used on **LAN** servers, where different sets of users share different files and applications. The maximum partition size in the first version of DOS to use FDISK was 16 **megabytes**. Recent Windows systems support hard drives up to 2 **terabytes** (2,000 **gigabytes**) in size!

If you need to repartition your current hard drive, be sure to back up all data because it will be lost when you use FDISK. Be careful to follow the documented Microsoft and manufacturer directions.

The age of your computer and the operating system you use determines how difficult the hard drive installation will be. The Basic Input Output System (**BIOS**) in computers manufactured before 1994 does not support drives larger than 512 MB, which causes FDISK to display larger hard drives as only 512 MB in size. It is necessary to use disk management software that helps an older BIOS version to recognize a hard drive larger than 512 MB. Disk management software is usually included with your new hard drive or free upon request from the hard drive manufacturer. You can also purchase a BIOS upgrade such as an **EPROM** chip, **flash memory** BIOS software, a controller card, or a card with a BIOS chip on it depending

on the manufacturer’s recommendation. Depending on your operating system, you may have to create multiple partitions in order to use your hard drive’s full capacity:

- DOS version 6.22 and later supports drives greater than 8.4 GB. Versions earlier than 6.22 do not.
- Windows 95A does support drives larger than 8.4 GB, but you have to partition the drive into at least four partitions depending on the hard drive’s size because of **FAT 16** file system’s limitations used by Windows 95A. Windows 95B supports **FAT 32**, which allows one large partition on new hard drives and supports hard drives up to 2,000 GB in size.
- The first and later editions of Windows 98 support **FAT 32** and hard drives up to 2,000 GB.
- Windows NT version 5.0 and later also supports large hard drives.

FDISK has its limitations. You can’t move applications from one partition to another without uninstalling and reinstalling the software. FDISK erases all data on your hard drive. And you can’t delete or create new partitions without going through the entire FDISK and formatting process again. However, special partitioning software such as PartitionMagic can be used instead of FDISK. Partitioning software allows you to create, delete, and resize partitions without losing your data. You can move applications from one partition to another without uninstalling and reinstalling the application. You can hide partitions to protect data from other users. You can also use partitioning software as a boot manager. A boot manager allows you to install and use more than one operating system easily. Partition software also eliminates the need for a BIOS upgrade in older computers.

FDM

See “frequency-division multiplexing”

FDMA

FDMA (frequency division multiple access) is the division of the frequency band allocated for **wireless cellular telephone** communication into 30 channels, each of which can carry a voice conversation or, with digital service, carry digital data. FDMA is a basic technology in the **analog** Advanced Mobile Phone Service (**AMPS**), the most widely-installed cellular phone system installed in North America. With FDMA, each channel can be assigned to only one user at a time. FDMA is also used in the Total Access Communication System (TACS).

The Digital-Advanced Mobile Phone Service (**D-AMPS**) also uses FDMA but adds time division multiple access (**TDMA**) to get three channels for each FDMA channel, tripling the number of calls that can be handled on a channel.

Federation of Telecommunications Engineers of the European Community

FITCE (Federation of Telecommunications Engineers of the European Community) is an international association that is committed to affecting telecommunication developments in a positive and constructive manner throughout Europe and the rest of the world. The FITCE Association informs and updates members and others engaged in the telecommunication industry. FITCE maintains a resource database for linking globally to telecommunication opportunities and contacts.

FITCE states that their aims are:

- To promote the development of science in the field of telecommunications.
- To enable each member to benefit from the experience acquired by the other members in all telecommunication fields (including associated areas, such as specialised buildings, power supplies and electrical machinery, electronic computers, and so forth) and to investigate new ideas that encourage the development of telecommunications in all countries represented.
- To study all aspects of problems arising from the recruitment, training, work assignments, and career structures of these telecommunications professionals.
- To develop cultural ties and to encourage friendly relations between telecommunications professionals who belong to the member associations, in order to enable themselves and their families to become better acquainted with one another.

feed line

In a **wireless** communications or broadcasting antenna system, the feed line connects the **antenna** to the receiver, transmitter, or transceiver. The line transfers radio-frequency (RF) energy from a transmitter to an antenna, and/or from an antenna to a receiver, but, if operating properly, does not radiate or intercept energy itself. There are three types of antenna feed lines, also called *RF transmission lines*, commonly used in wireless systems.

Coaxial line, also called **coaxial cable**, consists of a wire conductor surrounded by a tubular, braided metallic shield. The conductor is kept at the center of the shield by a **dielectric**, which is usually solid or foamed polyethylene. The shield is connected to RF ground, while the center conductor carries the **signal**. The shield, as its name implies, prevents the **electromagnetic field** (EM field) inside the

cable from escaping, and also prevents EM energy from entering the cable from outside. Coaxial cables are used at frequencies below approximately 1 **gigahertz**.

Parallel-wire line consists of two wires running alongside each other. At each point along the line, the RF **current** in the two wires are always equal in magnitude but opposite in direction. The two wires are spaced close together in terms of the EM **wavelength**. Because of this, the EM fields from the two wires practically cancel out each other in the region outside the line. This prevents the line from radiating RF energy. In receiving systems, EM fields from the external environment induce RF currents that flow in the same direction in each conductor. The receiver circuitry cancels out RF currents that flow in the same direction in both conductors, while responding to RF currents that flow in opposite directions. This prevents external EM fields from affecting the line. Parallel-wire line is rarely employed in commercial installations, but a prefabricated form, called *TV ribbon*, is sometimes used with television receivers in fringe areas for reception of channels 2 through 13. Another type of two-wire line, known as *window line*, *ladder line*, or *open wire*, is popular among **amateur radio** operators and shortwave listeners.

A **waveguide** is a hollow, metallic tube or pipe with a circular or rectangular cross section. The diameter of the waveguide is comparable to the wavelength of the EM field. The EM field travels along the inside of the waveguide in a manner somewhat analogous to the way sound waves propagate down a narrow tunnel. The metal structure prevents EM fields inside the waveguide from escaping, and also prevents external EM fields from penetrating to the interior. Waveguides are used at microwave frequencies, that is, at 1 GHz and above.

Because the currents in a parallel-wire line always exactly cancel or balance each other, this type of line constitutes a *balanced feed line*. Such lines work best with antenna systems that are bilaterally symmetrical; an example is the **dipole antenna**. Coaxial cables and waveguides are *unbalanced feed lines*. This type of line will work satisfactorily with antennas that are not symmetrical. With the use of a transformer called a **balun** (contraction of the words "balanced" and "unbalanced"), coaxial cables and waveguides can be used with symmetrical antennas.

femtosecond

(This definition follows U.S. usage in which a billion is a thousand million and a trillion is a 1 followed by 12 zeros.)

A femtosecond is one millionth of a nanosecond or 10^{-15} of a second and is a measurement sometimes used in laser technology.

For comparison, a millisecond (ms or msec) is one thousandth of a second and is commonly used in measuring the time to read to or write from a **hard disk** or a **CD-ROM** player or to measure **packet** travel time on the Internet.

A microsecond (μs) is one millionth (10^{-6}) of a second.

A nanosecond (ns or nsec) is one billionth (10^{-9}) of a second and is a common measurement of read or write access time to random access memory (RAM).

A picosecond is one trillionth (10^{-12}) of a second, or one millionth of a microsecond.

An attosecond is one quintillionth (10^{-18}) of a second and is a term used in photon research.

ferret

In a computer or a network, a ferret is a program that searches through selected files, databases, or search engine indexes for information that meets specified search criteria. The term derives from the name of a small furry animal, commonly a pet, that burrows under things. On the Internet, a ferret can forward a request simultaneously to a number of search engine sites and filter the results according to user-specified or program-designed guidelines.

Ferrets can be written to search a specific group of World Wide Web search engine sites, Usenet news groups, global e-mail directories, Internet Relay Channel (IRC) member lists, and any public, searchable database that can be efficiently selected.

A ferret should not be confused with a crawler, a program that search engines use to gather data from many Web pages that is then indexed for search retrieval.

ferroelectric RAM

See "FRAM"

ferrule

A ferrule (from Latin *viriola*, meaning *little bracelet*) is a ring or cap attached to an object to protect against damage, splitting, or wear. In fiber optics, a ferrule is a component (usually a rigid tube) used to align and protect the stripped end of a fiber.

A ferrule is used together with the connector that connects the fiber cable either to another cable or to a transmitter or receiver. The ferrule keeps the fibers accurately aligned within the connector. Ferrules can be made of glass, plastic, metal, or ceramic material. Ceramic is currently considered the best material for a number of reasons. For example, ceramic bonds well to glass and its expansion coefficient is close to that of the glass fibers, making it environmentally stable.

FET

See "field-effect transistor"

fetch

In computer technology, fetch has several meanings related to getting, reading, or moving data objects.

1) Fetch is the first of two stages involved in computer processing. The processor operates by processing instructions in what is called the "fetch/execute cycle." The processor fetches (reads from memory) an instruction and then, depending on the instruction, executes it (takes some further action with it, such as shifting bits to the right or left). Then it fetches the next instruction, and so forth.

A register in the processor called the program counter holds information about where the processor is in the particular program being processed and the address (location) of the next instruction to be executed. At the beginning of the cycle, the program counter tells the processor which instruction to fetch; during the cycle, the instruction is executed and the information is updated to refer to the next instruction to be fetched.

In some newer processor designs, more than one instruction can be fetched at the same time and execution is done in parallel.

2) Fetch is a command used in embedded Structured Query Language (SQL) to retrieve rows sequentially. In SQL, a cursor is a pointer to a selected row in a collection retrieved by a SQL statement. The cursor advances through the rows, one at a time, to allow sequential processing of records. The fetch command retrieves the selected row from the cursor. The steps involved in using the fetch command are: Declare cursor, Open cursor, Fetch row (separate fetches may be executed for multiple rows) and Close cursor.

3) Fetch is a Macintosh program for transferring files between any networked Macintosh computers using the File Transfer Protocol (FTP). Its features include support of multiple connections, the capacity to restart interrupted transfers, and drag-and-drop functionality for transferring, bookmarking, and preference setting.

FH-CDMA

See "frequency-hopping spread spectrum"

Fiber Connectivity

See "FICON"

Fiber Distributed Data Interface

See "FDDI"

fiber optic

Fiber optic (or "optical fiber") refers to the medium and the technology associated with the transmission of information as light impulses along a glass or plastic wire or fiber. Fiber optic wire carries much more information than conventional copper wire and is far less subject to electromagnetic interference. Most telephone company long-distance lines are now fiber optic.

Transmission on fiber optic wire requires repeating at distance intervals. The glass fiber requires more protection within an outer cable than copper. For these reasons and because the installation of any new wiring is labor-intensive, few communities yet have fiber optic wires or cables from the phone company's branch office to local customers (known as **local loop**).

fiber to the curb

"Fiber to the curb" (FTTC) refers to the installation and use of **optical fiber** cable directly to the curbs near homes or any business environment as a replacement for "plain old telephone service" (**POTS**). Think of removing all the telephone lines you see in your neighborhood and replacing them with optical fiber lines. Such wiring would give us extremely high **bandwidth** and make possible movies-on-demand and online multimedia presentations arriving without noticeable delay.

The term "fiber to the curb" recognizes that optical fiber is already used for most of the long-distance part of your telephone calls and Internet use. Unfortunately, the last part—installing fiber to the curb—is the most expensive. For this reason, fiber to the curb is proceeding very slowly. Meanwhile, other less costly alternatives, such as **Asymmetric Digital Subscriber Line** on regular phone lines and satellite delivery, are likely to arrive much sooner in most homes.

Fiber to the curb implies that **coaxial cable** or another medium might carry the signals the very short distance between the curb and the user inside the home or business. "Fiber to the building" (FTTB) refers to installing optical fiber from the telephone company central office to a specific building such as a business or apartment house. "Fiber to the neighborhood" (FTTN) refers to installing it generally to all curbs or buildings in a neighborhood. Hybrid Fiber Coax (**HFC**) is an example of a distribution concept in which optical fiber is used as the **backbone** medium in a given environment and coaxial cable is used between the backbone and individual users (such as those in a small corporation or a college environment).

fiberless optics

Fiberless optics, a term that has been trademarked by TeraBeam Networks, is a technology for transmitting large amounts of data on light waves sent through space rather than along an **optical fiber** cable, thus offering a surprising new solution to the so-called **last-mile technology** problem. Until now, optical fiber, cable TV, and various forms of **wireless** transmission have been the alternatives to consider in getting data back and forth between the backbone network and the home or business. TeraBeam Networks, a Seattle, Washington, company, expects to offer its "wireless optical fiber" system for mainly corporate use beginning in the summer of 2000 and to offer it in international markets over the next three years.

TeraBeam describes the system as providing **broadband** services from a highly-directional point-to-multipoint beam using frequencies that "operate in a region of the **electromagnetic radiation spectrum** that is not subject to regulation by the FCC." The signal is **encryption** and said to be almost impossible to intercept. Multiple connections offer **scalability** and can be close together without interference concerns. The service will support the Internet Protocol (**IP**). As described by TeraBeam, fiberless optics seems like a laser beam (using a different part of the spectrum perhaps) that can be set up over a relatively long distance within a city-wide area. The system would involve fixed (not mobile) connections.

Fibre Channel over IP

Fibre Channel over IP (FC/IP, also known as *Fibre Channel tunneling* or *storage tunneling*) is an Internet Protocol (**IP**)-based storage networking technology developed by the Internet Engineering Task Force (**IETF**). FC/IP mechanisms enable the transmission of **Fibre Channel** (FC) information by **tunneling** data between storage area network (**SAN**) facilities over IP networks; this capacity facilitates data sharing over a geographically distributed enterprise. One of two main approaches to storage data transmission over IP networks, FC/IP is among the key technologies expected to help bring about rapid development of the storage area network market by increasing the capabilities and performance of storage data transmission.

FC/IP Versus iSCSI

The other method, **iSCSI**, generates **SCSI** codes from user requests and encapsulates the data into **IP packets** for transmission over an **Ethernet** connection. Intended to link geographically distributed SANs, FC/IP can only be used in conjunction with Fibre Channel technology; in comparison, iSCSI can run over existing Ethernet networks. SAN connectivity, through methods such as FC/IP and iSCSI, offers benefits over the traditional point-to-point connections of earlier data storage systems, such as higher performance, availability, and **fault-tolerance**. A number of vendors, including Cisco, Nortel, and Lucent have introduced FC/IP-based products (such as **switches** and **routers**). Both iSCSI and FC/IP are proposed standards, and are expected to be ratified by the end of 2001. A hybrid technology called *Internet Fibre Channel Protocol* (iFCP) is an adaptation of FC/IP that is used to move Fibre Channel data over IP networks using the iSCSI protocols.

Fibre Channel

Fibre Channel is a technology for transmitting data between computer devices at a data rate of up to 1 **Gbps**, or one billion bits per second. (A data rate of 10 Gbps has been proposed by the Fibre Channel Industry Association.) Fibre Channel is especially suited for connecting computer **servers** to shared storage devices and for interconnecting storage

controllers and drives. Since Fibre Channel is three times as fast, it has begun to replace the Small Computer System Interface (SCSI) as the transmission interface between servers and clustered storage devices. Fibre channel is more flexible; devices can be as far as ten kilometers (about six miles) apart if **optical fiber** is used as the physical medium. Optical fiber is not required for shorter distances, however, because Fibre Channel also works using **coaxial cable** and ordinary telephone **twisted pair**.

Fibre Channel offers point-to-point, switched, and loop interfaces. It is designed to interoperate with SCSI, the Internet Protocol (IP) and other protocols, but has been criticized for its lack of compatibility—primarily because (like in the early days of SCSI technology) manufacturers sometimes interpret specifications differently and vary their implementations.

Standards for Fibre Channel are specified by the Fibre Channel Physical and Signalling standard, and the ANSI X3.230-1994, which is also ISO 14165-1.

FICON

FICON (for *Fiber Connectivity*) is a high-speed input/output (I/O) **interface** for **mainframe** computer connections to storage devices. As part of IBM's S/390 server, FICON channels increase I/O capacity through the combination of a new architecture and faster physical link rates to make them up to eight times as efficient as ESCON (Enterprise System Connection), IBM's previous **fiber optic** channel standard.

FICON **channel** features include:

- A mapping layer based on the ANSI standard Fibre Channel-Physical and Signaling Interface (FC-PH), which specifies the signal, cabling, and transmission speeds
- 100 **Mbps** bi-directional link rates at distances of up to twenty kilometers, compared to the 3Mbps rate of ESCON channels at distances of up to three kilometers.
- More flexibility in terms of network layout, because of the greater distances
- Compatibility with any installed channel types on any S/390 G5 server
- Bridge feature, which enables support of existing ESCON control units
- Requires only one channel address
- Support for **full-duplex** data transfers, which enables simultaneous reading and writing of data over a single link
- **Multiplexing**, which enables small data transfers to be transmitted with larger ones, rather than having to wait until the larger transaction is finished

FidoNet

Started in 1984, FidoNet is a system for exchanging e-mail and discussion group and other files among users of over 30,000 bulletin board services. FidoNet messages are sent using the UNIX-to-UNIX Copy Protocol (**UUCP**). Messages can travel over the Internet after being converted to **TCP/IP** format by computer servers that act as Internet **gateway**.

field emission display

A field emission display (FED) is a new type of flat-panel display in which electron emitters, arranged in a grid, are individually controlled by “cold” cathodes to generate colored light. Field emission display technology makes possible the thin panel of today's liquid crystal displays (**LCD**), offers a wider field-of-view, provides the high image quality of today's cathode ray tube (**CRT**) displays, and requires less power than today's CRT displays.

Some FED products are now available and developers continue to refine the technology. Two companies working on this technology are Candescant Technologies and PixTech.

field

A field is an area in a fixed or known location in a unit of data such as a **record**, message **header**, or computer **instruction** that has a purpose and usually a fixed size. A field can be subdivided into smaller fields. Here are some examples:

- 1) In a form that you fill out on a Web site, each box that asks you for information is a text entry field.
- 2) In the **header** of a variable-length transmission unit, a two-byte subfield in the header (which is really a field itself) could identify the length in bytes of the message.

field-effect transistor

See also **bipolar transistor** and **transistor**.

A field-effect transistor (FET) is a type of **transistor** commonly used for weak-signal amplification (for example, for amplifying **wireless** signals). The device can amplify **analog** or **digital** signals. It can also switch DC or function as an oscillator.

In the FET, current flows along a semiconductor path called the *channel*. At one end of the channel, there is an electrode called the *source*. At the other end of the channel, there is an electrode called the *drain*. The physical diameter of the channel is fixed, but its effective electrical diameter can be varied by the application of a voltage to a control electrode called the *gate*. The conductivity of the FET depends, at any given instant in time, on the electrical diameter of the channel. A small change in gate voltage can cause a large variation in the current from the source to the drain. This is how the FET amplifies signals.

Field-effect transistors exist in two major classifications. These are known as the *junction FET (JFET)* and the *metal-oxide-semiconductor FET (MOSFET)*.

The junction FET has a channel consisting of N-type semiconductor (N-channel) or P-type semiconductor (P-channel) material; the gate is made of the opposite semiconductor type. In P-type material, electric charges are carried mainly in the form of **electron** deficiencies called *holes*. In N-type material, the charge carriers are primarily electrons. In a JFET, the junction is the boundary between the channel and the gate. Normally, this P-N junction is reverse-biased (a DC voltage is applied to it) so that no current flows between the channel and the gate. However, under some conditions there is a small current through the junction during part of the input signal cycle.

In the MOSFET, the channel can be either N-type or P-type semiconductor. The gate electrode is a piece of metal whose surface is oxidized. The oxide layer electrically insulates the gate from the channel. For this reason, the MOSFET was originally called the *insulated-gate FET (IGFET)*, but this term is now rarely used. Because the oxide layer acts as a dielectric, there is essentially never any current between the gate and the channel during any part of the signal cycle. This gives the MOSFET an extremely large input **impedance**. Because the oxide layer is extremely thin, the MOSFET is susceptible to destruction by electrostatic charges. Special precautions are necessary when handling or transporting MOS devices.

The FET has some advantages and some disadvantages relative to the **bipolar transistor**. Field-effect transistors are preferred for weak-signal work, for example in **wireless** communications and broadcast receivers. They are also preferred in circuits and systems requiring high impedance. The FET is not, in general, used for high-power amplification, such as is required in large wireless communications and broadcast transmitters.

Field-effect transistors are fabricated onto silicon integrated circuit (IC) chips. A single IC can contain many thousands of FETs, along with other components such as resistors, capacitors, and diodes.

field-programmable gate array

A field-programmable gate array (FPGA) is an integrated circuit (IC) that can be programmed in the field after manufacture. FPGAs are similar in principle to, but have vastly wider potential application than, programmable read-only memory (PROM) chips. FPGAs are used by engineers in the design of specialized ICs that can later be produced hard-wired in large quantities for distribution to computer manufacturers and end users. Ultimately, FPGAs might allow computer users to tailor microprocessors to meet their own individual needs.

FIFO

Also see **named pipe** (sometimes referred to as a "fifo").

In computer programming, FIFO (first-in, first-out) is an approach to handling program work requests from **queues** or **stacks** so that the oldest request is handled next. LIFO (last-in, first-out) is an approach in which the most recent request is handled next and the oldest request doesn't get handled until it is the only remaining request on the queue (or in the stack). Although LIFO seems "unfair," it may be more efficient. A stack that is handled using LIFO is sometimes referred to as a *push-down* or *push-down pop-up* stack or list.

file

1) In data processing, using an office metaphor, a file is a related collection of records. For example, you might put the records you have on each of your customers in a file. In turn, each **record** would consist of *fields* for individual data items, such as customer name, customer number, customer address, and so forth. By providing the same information in the same fields in each record (so that all records are consistent), your file will be easily accessible for analysis and manipulation by a computer program. This use of the term has become somewhat less important with the advent of the **database** and its emphasis on the table as a way of collecting record and field data. In mainframe systems, the term **data set** is generally synonymous with file but implies a specific form of organization recognized by a particular **access method**. Depending on the operating system, files (and data sets) are contained within a **catalog**, **directory**, or **folder**.

2) In any computer system but especially in personal computers, a file is an entity of data available to system users (including the system itself and its application programs) that is capable of being manipulated as an entity (for example, moved from one file directory to another). The file must have a unique name within its own directory. Some operating systems and applications describe files with given formats by giving them a particular file name suffix. (The file name suffix is also known as a file name **extension**.) For example, a program or executable file is sometimes given or required to have an ".exe" suffix. In general, the suffixes tend to be as descriptive of the formats as they can within the limits of the number of characters allowed for suffixes by the operating system.

file allocation table

Also see: **fat Mac** and **Virtual File Allocation Table**.

A file allocation table (FAT) is a table that an **operating system** maintains on a **hard disk** that provides a map of the **clusters** (the basic units of logical storage on a hard disk) that a file has been stored in. When you write a new file to a hard disk, the file is stored in one or more clusters that are not necessarily next to each other; they may be rather widely

scattered over the disk. A typical cluster size is 2,048 **bytes**, 4,096 bytes, or 8,192 bytes. The operating system creates a FAT entry for the new file that records where each cluster is located and their sequential order. When you read a file, the operating system reassembles the file from clusters and places it as an entire file where you want to read it. For example, if this is a long Web page, it may very well be stored on more than one cluster on your hard disk.

Until Windows 95 **OSR2** (OEM Release 2), DOS and Windows file allocation table entries were 16 bits in length, limiting hard disk size to 128 **megabytes**, assuming a 2,048 size cluster. Up to 512 megabyte support is possible assuming a cluster size of 8,192 but at the cost of using clusters inefficiently. DOS 5.0 and later versions provide for support of hard disks up to two **gigabytes** with the 16-bit FAT entry limit by supporting separate FATs for up to four partitions.

With 32-bit FAT entry (FAT32) support in Windows 95 OSR2, the largest size hard disk that can be supported is two **terabytes!** However, personal computer users are more likely to take advantage of FAT32 with 5 or 10 gigabyte drives.

file carbon copy

See “Fcc”

file sharing

File sharing is the public or private sharing of computer **data** or space in a **network** with various levels of **access** privilege. While **files** can easily be shared outside a network (for example, simply by handing or mailing someone your file on a diskette), the term *file sharing* almost always means sharing files in a network, even if in a small local area network. File sharing allows a number of people to use the same file or file by some combination of being able to read or view it, write to or modify it, copy it, or print it. Typically, a file sharing system has one or more administrators. Users may all have the same or may have different levels of access privilege. File sharing can also mean having an allocated amount of personal file storage in a common file system.

File sharing has been a feature of **mainframe** and multi-user computer systems for many years. With the advent of the Internet, a file transfer system called the File Transfer Protocol (**FTP**) has become widely-used. FTP can be used to access (read and possibly write to) files shared among a particular set of users with a password to gain access to files shared from an FTP server site. Many FTP sites offer public file sharing or at least the ability to view or copy files by downloading them, using a public password (which happens to be “anonymous”). Most Web site developers use FTP to upload new or revised Web files to a Web server, and indeed the World Wide Web itself can be thought of as

large-scale file sharing in which requested pages or files are constantly being downloaded or copied down to the Web user.

More usually, however, file sharing implies a system in which users write to as well as read files or in which users are allotted some amount of space for personal files on a common server, giving access to other users as they see fit. The latter kind of file sharing is common in schools and universities. File sharing can be viewed as part of file systems and their management.

Any multi-user operating system will provide some form of file sharing. Among the best known network file systems is (not surprisingly) the Network File System (**NFS**). Originally developed by Sun Microsystems for its **UNIX**-based systems, it lets you read and, assuming you have permission, write to sharable files as though they were on your own personal computer. Files can also be shared in file systems distributed over different points in a network. File sharing is involved in groupware and a number of other types of applications.

file system

1) In a computer, a file system is the way in which **files** are named and where they are placed logically for storage and retrieval. The DOS, Windows, OS/2, Macintosh, and UNIX-based operating systems all have file systems in which files are placed somewhere in a hierarchical (tree) structure. A file is placed in a **directory** (*folder* in Windows) or subdirectory at the desired place in the tree structure.

File systems specify conventions for naming files. These conventions include the maximum number of characters in a name, which characters can be used, and, in some systems, how long the file name **suffix** can be. A file system also includes a format for specifying the **path** to a file through the structure of directories.

2) Sometimes the term refers to the part of an operating system or an added-on program that supports a file system as defined in (1). Examples of such add-on file systems include the Network File System (**NFS**) and the Andrew file system (**AFS**).

File Transfer Protocol

File Transfer Protocol (**FTP**), a standard Internet **protocol**, is the simplest way to exchange files between computers on the Internet. Like the Hypertext Transfer Protocol (**HTTP**), which transfers displayable Web pages and related files, and the Simple Mail Transfer Protocol (**SMTP**), which transfers e-mail, FTP is an application protocol that uses the Internet’s **TCP/IP** protocols. FTP is commonly used to transfer Web page files from their creator to the computer that acts as their **server** for everyone on the Internet. It’s also commonly used to **download** programs and other files to your computer from other servers.

As a user, you can use FTP with a simple command line interface (for example, from the Windows MS-DOS Prompt window) or with a commercial program that offers a graphical user interface. Your Web browser can also make FTP requests to download programs you select from a Web page. Using FTP, you can also update (delete, rename, move, and copy) files at a server. You need to **logon** to an FTP server. However, publicly available files are easily accessed using **anonymous FTP**.

Basic FTP support is usually provided as part of a suite of programs that come with TCP/IP. However, any FTP client program with a graphical user interface usually must be downloaded from the company that makes it.

file transfer

File transfer is the movement of one or more **files** from one location to another. A collection of electronically-stored files can be moved by physically moving the electronic storage medium, such as a computer **diskette**, **hard disk**, or **compact disk** from one place to another or by sending the files over a telecommunications medium. On the Internet, the File Transfer Protocol (**FTP**) is a common way to transfer a single file or a relatively small number of files from one computer to another. For larger file transfers (a single large file or a large collection of files), file **compression** and aggregation into a single **archive** is commonly used. (A **zip file** is a popular implementation.)

Electronic Data Interchange (**EDI**) is a popular **protocol** for transferring files in a routine manner between businesses.

FileMaker

FileMaker (or its latest version, FileMaker Pro) is a **relational database** application known for being easy to use and for its ability to serve **Web pages** dynamically without requiring the use of additional third-party applications. With its built-in Web server (called "Web Companion") and out-of-the-box business **templates**, FileMaker Pro has received high praise for being the ideal application for beginning Web site administrators who want to quickly (literally with one click) add Web database publishing capabilities to their Web site or company intranet.

FileMaker was originally developed as a personal database application for the **Macintosh** computer by the Claris Corporation and has since moved into the Windows market. In an effort to build upon FileMaker's reputation for user friendliness, FileMaker Pro (now its latest version, FMP5) has been purposely redesigned so that its user interface more closely resembles that of Microsoft's Office. FMP5 has two Web publishing modes: Instant Web Publishing (which uses pre-designed templates and requires no knowledge of **HTML**) and Custom Web Publishing, which requires knowledge of **HTML** and Web Companion's proprietary programming language and is called Claris Dynamic Markup Language (CDML).

FMP5 can be used with a wide variety of **middleware** applications, common gateway interface (**CGI scripts**), and **application servers** to provide additional Web capabilities. For instance, to provide Secure Socket Layer (**SSL**) support, FMP5 can be connected to a **Mac OS** server by using WebStar, or be connected to a **Windows NT server** by using Microsoft's Web Server. To increase scalability, it is possible to set up a redundant array of inexpensive computers (**RAID**) to provide **load balancing** and to ensure consistent page serving with multiples copies of File Maker Pro 5 Unlimited.

FMP has also teamed up with **Palm** to provide database administrators with a way to seamlessly integrate information in a FMP database with Palm's Wireless Internet service.

filter

1) In computer programming, a filter is a program or section of code that is designed to examine each input or output request for certain qualifying criteria and then process or forward it accordingly. This term was used in **UNIX** systems and is now used in other operating systems. A filter is "pass-through" code that takes input data, makes some specific decision about it and possible transformation of it, and passes it on to another program in a kind of pipeline. Usually, a filter does no input/output operation on its own. Filters are sometimes used to remove or insert headers or control characters in data.

In Windows operating systems, using Microsoft's Internet Server Application Programming Interface (**ISAPI**), you can write a filter (in the form of a dynamic link library or **DLL** file) that the operating system gives control each time there is a Hypertext Transport Control (**HTTP**) request. Such a filter might log certain or all requests or encrypt data or take some other selective action.

2) In telecommunications, a filter is a device that selectively sorts signals and passes through a desired range of signals while suppressing the others. This kind of filter is used to suppress noise or to separate signals into **bandwidth** channels.

Financial Products Markup Language

See "FpML"

Financial Services Markup Language

FSML (Financial Services Markup Language) is a data description language based on the Standard Generalized Markup Language (**SGML**) that was developed to create financial documents for delivery over the Internet, including **eCheck** and their associated documentation. Like the Hypertext Markup Language (**HTML**), FSML is a set of **markup** symbols or codes that allows its users to define the individual items that compose a document, assemble items

into larger document parts that take on a contextual meaning, and enable the screening of a document for **digital signatures**, endorsement, additions, or deletions.

FSML was created to ensure that eChecks could be transmitted by e-mail without being corrupted or invalidated by the particular e-mailing system in use. In order to make sure that all data contents are defined as specifically as possible and therefore may be processed by a software application in their entirety, FSML requires precise adherence to definitions of **syntax**, **semantics**, and all values associated with data elements.

FSML is designed to support a full range of payment mechanisms, including electronic checks, Automatic Clearing House (ACH) payment authorizations, ATM network transaction authorizations, and variations of a check, such as a postal money order or gift certificate. In the near future, FSML is expected to conform to the Extensible Markup Language (XML).

finger

Finger is a program that tells you the name associated with an **e-mail** address. It may also tell you whether they are currently logged in at their system or their most recent logon session and possibly other information, depending on the data that is maintained about users on that computer. Finger originated as part of **BSD UNIX**.

To finger another Internet user, you need to have the finger program on your computer or you can go to a **finger gateway** on the Web and enter the e-mail address. The server at the other end must be set up to handle finger requests. A “.plan” file can be created for any user that can be fingered. Commonly, colleges, universities, and large corporations set up a finger facility. Your own Internet access provider may also set up information about you and other subscribers that someone else can “finger.” (To find out, enter your own e-mail address at a finger gateway.)

Ph and LDAP are somewhat similar facilities.

finite state machine

In general, a state machine is any device that stores the status of something at a given time and can operate on input to change the status and/or cause an action or output to take place for any given change. A **computer** is basically a state machine and each machine **instruction** is input that changes one or more states and may cause other actions to take place. Each computer’s data register stores a state. The **read-only memory** from which a **boot** program is loaded stores a state (the boot program itself is an initial state). The **operating system** is itself a state and each **application** that runs begins with some initial state that may change as it begins to handle input. Thus, at any moment in time, a computer system can be seen as a very complex set of states and each program in

it as a state machine. In practice, however, state machines are used to develop and describe specific device or program interactions.

To summarize it, a state machine can be described as:

- An initial state or record of something stored someplace
- A set of possible input events
- A set of new states that may result from the input
- A set of possible actions or output events that result from a new state

In their book *Real-time Object-oriented Modeling*, Bran Selic & Garth Gullekson view a state machine as:

- A set of input events
- A set of output events
- A set of states
- A function that maps states and input to output
- A function that maps states and inputs to states (which is called a state transition function)
- A description of the initial state

A finite state machine is one that has a limited or finite number of possible states. (An infinite state machine can be conceived but is not practical.) A finite state machine can be used both as a development tool for approaching and solving problems and as a formal way of describing the solution for later developers and system maintainers. There are a number of ways to show state machines, from simple tables through graphically animated illustrations.

FIPS

FIPS (Federal Information Processing Standards) are a set of standards that describe document processing, provide standard algorithms for searching, and provide other information processing standards for use within U.S. government agencies.

firewall

A firewall is a set of related programs, located at a network **gateway server**, that protects the resources of a private network from users from other networks. (The term also implies the security policy that is used with the programs.) An enterprise with an **intranet** that allows its workers access to the wider Internet installs a firewall to prevent outsiders from accessing its own private data resources and for controlling what outside resources its own users have access to.

Basically, a firewall, working closely with a **router** program, examines each network **packet** to determine whether to forward it toward its destination. A firewall also includes or works with a **proxy server** that makes network requests on behalf of workstation users. A firewall is often installed in a

specially designated computer separate from the rest of the network so that no incoming request can get directly at private network resources.

There are a number of firewall screening methods. A simple one is to screen requests to make sure they come from acceptable (previously identified) **domain name** and **Internet Protocol** addresses. For mobile users, firewalls allow remote access in to the private network by the use of secure logon procedures and authentication certificates.

A number of companies make firewall products. Features include logging and reporting, automatic alarms at given thresholds of attack, and a graphical user interface for controlling the firewall.

FireWire

FireWire is Apple Computer's version of a standard, **IEEE 1394**, High Performance Serial Bus, for connecting devices to your personal computer. FireWire provides a single plug-and-socket connection on which up to 63 devices can be attached with data transfer speeds up to 400 **Mbps** (megabits per second). The standard describes a **serial bus** or pathway between one or more peripheral devices and your computer's **microprocessor**. Many peripheral devices now come equipped to meet IEEE 1394. FireWire and other IEEE 1394 implementations provide:

- A simple common plug-in serial connector on the back of your computer and on many different types of peripheral devices
- A thin serial cable rather than the thicker parallel cable you now use to your printer, for example
- A very high-speed rate of data transfer that will accommodate multimedia applications (100 and 200 megabits per second today; with much higher rates later)
- Hot-plug and **plug and play** capability without disrupting your computer
- The ability to chain devices together in a number of different ways without terminators or complicated set-up requirements

In time, IEEE 1394 implementations are expected to replace and consolidate today's serial and parallel interfaces, including **Centronics parallel**, **RS-232C**, and Small Computer System Interface (**SCSI**). The first products to be introduced with FireWire include **digital cameras**, digital video disks (**DVDs**), digital video tapes, digital camcorders, and music systems. Because IEEE 1394 is a **peer-to-peer** interface, one camcorder can dub to another without being plugged into a computer. With a computer equipped with the socket and bus capability, any device (for example, a video camera) can be plugged in while the computer is running.

Briefly How It Works

There are two levels of interface in IEEE 1394, one for the **backplane** bus within the computer and another for the point-to-point interface between device and computer on the serial cable. A simple bridge connects the two environments. The backplane bus supports 12.5, 25, or 50 megabits per second data transfer. The cable interface supports 100, 200, or 400 megabits per second. Each of these interfaces can handle any of the possible data rates and change from one to another as needed.

The serial bus functions as though devices were in slots within the computer sharing a common memory space. A 64-bit device address allows a great deal of flexibility in configuring devices in chains and trees from a single socket.

IEEE 1394 provides two types of data transfer: asynchronous and **isochronous**. Asynchronous is for traditional load-and-store applications where data transfer can be initiated and an application interrupted as a given length of data arrives in a **buffer**. Isochronous data transfer ensures that data flows at a pre-set rate so that an application can handle it in a timed way. For multimedia applications, this kind of data transfer reduces the need for buffering and helps ensure a continuous presentation for the viewer.

The 1394 standard requires that a device be within 4.5 meters of the bus socket. Up to 16 devices can be connected in a single chain, each with the 4.5 meter maximum (before signal attenuation begins to occur) so theoretically you could have a device as far away as 72 meters from the computer.

Another new approach to connecting devices, the Universal Serial Bus (**USB**), provides the same "hot plug" capability as the 1394 standard. It's a less expensive technology but data transfer is limited to 12 Mbps (million bits per second). Small Computer System Interface offers a high data transfer rate (up to 40 megabytes per second) but requires address preassignment and a device terminator on the last device in a chain. FireWire can work with the latest internal computer **bus** standard, Peripheral Component Interconnect (**PCI**), but higher data transfer rates may require special design considerations to minimize undesired buffering for transfer rate mismatches.

firmware

Firmware is programming that is inserted into programmable read-only memory (programmable **ROM**), thus becoming a permanent part of a computing device. Firmware is created and tested like software (using microcode simulation). When ready, it can be distributed like other software and, using a special user interface, installed in the programmable read-only memory by the user. Firmware is sometimes distributed for printers, modems, and other computer devices.

IBM prefers the term **microcode**.

first mover

In the business world, a first mover is a company that aims to gain an advantageous and perhaps insurmountable market position by being the first to establish itself in a given market. Since the arrival of the World Wide Web, many new companies (called “start-ups” until their **IPO**) have established themselves as first movers in their respective marketplace on the Web. Perhaps the quintessential example of being a first mover on the Web is Yahoo, which provided early Web users with the first popular directory and search engine. Although Yahoo has competition from Alta Vista, Google, and several other companies, its well-entrenched position as the one that got there first along with its easy-to-remember brand name and aggregation of content combine to make it difficult to compete with.

Other examples of first movers include Amazon.com (books), Travelocity (airline tickets), and eBay (online auctions). Although each of these has encountered competition, their early arrival and commitment to becoming the predominant owner of their market has seemed to assure their success.

One of the usual creeds of companies that attempt to be a first mover and command a market niche is “go big or stay home (**GOBOSH**).” Once a first mover has become established, the fact that someone has already arrived becomes in itself a **barrier to entry** for prospective competitors.

fixed wireless

Fixed wireless refers to the operation of **wireless** devices or systems in fixed locations such as homes and offices. Fixed wireless devices usually derive their electrical power from the utility mains, unlike **mobile wireless** or **portable wireless** which tend to be battery-powered. Although mobile and portable systems can be used in fixed locations, efficiency and **bandwidth** are compromised compared with fixed systems. Mobile or portable, battery-powered wireless systems can serve as emergency backups for fixed systems in case of a power blackout or natural disaster.

The technology for wireless connection to the Internet is as old as the Internet itself. Amateur radio operators began “patching” into telephone lines with fixed, mobile, and portable two-way voice radios in the middle of the 20th century. A wireless modem works something like an amateur-radio “phone patch,” except faster. High-end fixed wireless employs broadband modems that bypass the telephone system and offer Internet access hundreds of times faster than twisted-pair hard-wired connections or cell-phone modems.

Some of the most important assets of fixed wireless are as follows.

- Subscribers can be added or moved (to a certain extent) without modifying the infrastructure.
- Subscribers in remote areas can be brought into a network without the need for stringing new cables or optical fibers across the countryside.
- Broad bandwidth is possible because there are no wires or cables to introduce **reactance** into the connection (reactance limits bandwidth by preventing signals higher than a certain **frequency** from efficiently propagating).
- As the number of subscribers increases, the connection cost per subscriber goes down.

flag

In programming, a flag is a predefined **bit** or bit sequence setting in a small data area that is used by a program either to remember something or to leave a sign for another program. For example, a three-bit flags field or data area in a message being exchanged by two programs might be set to one of three bit configurations or flags:

001 (meaning “I’m a self-contained message”)

011 (meaning “I’m one of several chunks of data in this message”)

111 (meaning “I’m the last chunk of data in this message”)

Flags have many uses.

flamebait

On the Internet, flamebait is a “posting” or note on a **Web site** discussion forum, an online **bulletin board**, a **Usenet newsgroup**, or other public forum that is intended to elicit the extremely strong responses characteristic of **flaming** and active public discussions. To be effective, flamebait should be a bit subtle (but not too subtle) so that potential flammers will “take the bait.” This term is similar to **troll**, which is an effort to get a reaction from readers but not necessarily for the purpose of eliciting flames.

Sometimes flamebait is used just to get a discussion started.

flaming

On the Internet, flaming is giving someone a verbal lashing in public. Often this is on a **Usenet** newsgroup but it could be on a Web forum or perhaps even as e-mail with copies to a distribution list. Unless in response to some rather obvious **flamebait**, flaming is poor **netiquette**. Certain issues tend to provoke emphatically stated responses, but flaming is often directed at a self-appointed expert rather than at the issues or information itself and is sometimes directed at unwitting but opinionated **newbies** who appear in a newsgroup.

flanging

Flanging is an **audio** process that combines two copies of the same **signal**, with the second delayed slightly, to produce a swirling effect. The process originated before digital effect

boxes and computer editing were available. The effect, invented in the early 1950s by Les Paul and later used by artists such as Jimi Hendrix and The Beatles, was originally created using two tape recorders.

Here's how the nondigital process worked: While the original sound was being played from Tape Recorder #1, a second copy of the same audio material was played back from Tape Recorder #2. This process alone creates a hollow sound caused by the slight irregularities in the phase relationship of the audio waveforms. To get the flanging effect, the speed of the second recording was altered slightly. This was done most often by pressing a finger lightly on the tape reel's "flange," the large metal circle that surrounds and contains the tape on its hub. This created a time delay in addition to the phase differences, making the effect more pronounced.

Today, digital simulations of the process have replaced the flanging effect that was created using reel-to-reel tape recorders. The basic concept remains the same. The software or hardware device delays a copy of the source audio, but instead uses a low frequency **oscillator** (LFO) to vary the speed of the copy's playback. (The oscillator moves in the range of 1-20 cycles per seconds to get the effect.) Feeding the processed signal back into the device to be processed again can get a more intense effect.

Guitarist Les Paul invented flanging. He and Mary Ford first made it popular in the early 1950s. Les Paul also invented the solid body electric guitar and many sound techniques in use today. The first completely digital electronic flanging unit was the Delta Lab Research CompuEffectron, introduced in the 1970s.

Flash

Flash, a popular authoring software developed by Macromedia, is used to create **vector graphics**-based animation programs with full-screen navigation interfaces, graphic illustrations, and simple interactivity in an antialiased, resizable file format that is small enough to stream across a normal modem connection. The software is ubiquitous on the Web, both because of its speed (vector-based animations, which can adapt to different display sizes and resolutions, play as they download) and for the smooth way it renders graphics. Flash files, unlike animated but rasterized **GIF** and **JPEG** files, are compact, efficient, and designed for optimized delivery.

flash memory

Flash memory (sometimes called "flash RAM") is a type of constantly-powered **nonvolatile memory** that can be erased and reprogrammed in units of memory called *blocks*. It is a variation of electrically erasable programmable read-only memory (**EEPROM**) which, unlike flash memory, is erased and rewritten at the byte level, which is slower than flash memory updating. Flash memory is often used to hold

control code such as the Basic Input/Output System (**BIOS**) in a personal computer. When BIOS needs to be changed (rewritten), the flash memory can be written to it in block (rather than byte) sizes, making it easy to update. On the other hand, flash memory is not useful as random access memory (**RAM**) because RAM needs to be addressable at the byte (not the block) level.

Flash memory gets its name because the microchip is organized so that a section of memory cells are erased in a single action or "flash." The erasure is caused by Fowler-Nordheim tunneling in which electrons pierce through a thin **dielectric material** to remove an electronic charge from a *floating gate* associated with each memory cell. Intel offers a form of flash memory that holds two bits (rather than one) in each memory cell, thus doubling the capacity of memory without a corresponding increase in price.

Flash memory is used in digital cellular phones, digital cameras, LAN switches, **PC Card** for notebook computers, digital set-up boxes, embedded controllers, and other devices.

flat file

Also see **flat file system**, an entirely different term.

A flat file is a **file** containing **records** that have no structured interrelationship. The term is frequently used to describe a textual document from which all word processing or other structure characters or **markup** have been removed. In usage, there is some ambiguity about whether such markings as line breaks can be included in a "flat file." In any event, many users would call a Microsoft Word document that has been saved as "text only" a "flat file." The resulting file contains records (lines of text of a certain uniform length) but no information, for example, about what size to make a line that is a title or that a program could use to format the document with a table of contents.

Another form of flat file is one in which table data is gathered in lines of ASCII text with the value from each table cell separated by a comma and each row represented with a new line. This type of flat file is also known as a **comma-separated values file** (CSV) file.

In *SQL for Dummies*, an introduction to **Structured Query Language**, Allen G. Taylor notes that the advantage of a flat file is that it takes up less space than a structured file. However, it requires the application to have knowledge of how the data is organized within the file. By using SQL and a **database** (rather than a collection of files in a file system), a user or an application is free from having to understand the location and layout of data (for example, the length of each item of data, its type of data, and its relationship to other data items).

In relational databases, *flat file* is sometimes used as a synonym for a *relation*.

flat file system

Also see **flat file**, an entirely different term.

A flat file system is a system of files in which every **file** in the system must have a different name. In Windows 95 and most other **operating systems** today, files are managed in a hierarchical file system with a hierarchy of directories and subdirectories, each containing a number of files (or subdirectories). The operating system allows more than one file to have the same name as long as it is stored in a different directory. Early versions of the Macintosh and DOS operating systems used a flat file system.

The term *flat file directory* is used to describe a file directory that can contain only files (no subdirectories).

flexible transistor

A flexible transistor is one which, unlike present, rigidly-structured **transistors**, can be successfully used in packages that can be curled up, wrapped, or bent, a quality that will enable users to—for example—have a display screen that can be rolled up. In October 1999, IBM announced that they had developed a very thin, flexible and inexpensive type of transistor that could actually be sprayed onto plastic.

Cherie Kagan, a materials scientist at IBM, led a study that was featured in the journal *Science*. Kagan wrote that the combination of an inorganic **semiconductor** that conducts electricity and an organic material that modulates the structure makes the procedure possible at room temperature. Researchers used a compound composed of an organic material, phenethylammonium, and an inorganic material, tin iodide. The two materials were combined in separate layers, to create a coating thinner than a human hair. Current research is exploring other materials that could be used in the same fashion.

Currently available transistors are made of materials that must undergo high-temperature processing, and consequently can only be placed on heat-resistant surfaces. The flexible transistor could be used to replace the amorphous silicon used in computer displays. Future applications of the technology could include, among numerous other possibilities, a computer screen that could be rolled up and carried in the user's pocket.

flip chip-pin grid array

See "FC-PGA"

floating point unit

An floating point unit (FPU), also known as a *numeric coprocessor*, is a **microprocessor** or special circuitry in a more general microprocessor that manipulates numbers more quickly than the basic microprocessor your computer uses. It does so by having a special set of instructions that focus entirely on large mathematical operations. A floating point

unit is often built into today's personal computers, but it is needed only for special applications such as graphic image processing or display. Personal computers that don't have floating point units can sometimes handle software that requires them by installing a floating point **emulator**.

Floating point numbers are numbers that are carried out to a certain decimal position (such as 2.17986). They are stored in three parts: the *sign* (plus or minus), the *significant* or *mantissa* which is the digits that are meaningful, and the *exponent* or order of magnitude of the significant, which determines the place to which the decimal point floats. Floating point numbers are binary (expressed in powers of 2).

Some software you might download from the World Wide Web, such as Macromedia's **Shockwave**, may require that your computer have a floating point unit. If it doesn't, you may be able to download an FPU emulator that will fool the software into thinking you have one.

floating-point operations per second

See "FLOPS"

floating-point unit

See "floating point unit"

flooding

In a **network**, flooding is the forwarding by a **router** of a **packet** from any **node** to every other node attached to the router except the node from which the packet arrived. Flooding is a way to distribute routing information updates quickly to every node in a large network. It is also sometimes used in **multicast** packets (from one source node to many specific nodes in a real or virtual network).

The Internet's Open Shortest Path First (**OSPF**) protocol, which updates router information in a network, uses flooding.

floppy

See "diskette"

FLOPS

In computers, FLOPS are floating-point operations per second. Floating-point is, according to IBM, "a method of encoding real numbers within the limits of finite precision available on computers." Using floating-point encoding, extremely long numbers can be handled relatively easily. A floating-point number is expressed as a basic number or *mantissa*, an exponent, and a number base or *radix* (which is often assumed). The number base is usually ten but may also be 2. Floating-point operations require computers with floating-point *registers*. The computation of floating-point

S
T
U
V,W
X,Y,Z

numbers is often required in scientific or real-time processing applications and FLOPS is a common measure for any computer that runs these applications.

In larger computers and parallel processing, computer operations can be measured in **megaflops**, **gigaflops**, and **teraflops**. Some computer scientists have at least begun to think about **petaflops**.

flow control

Flow control is the management of data flow between computers or devices or between nodes in a network so that the data can be handled at an efficient pace. Too much data arriving before a device can handle it causes data overflow, meaning the data is either lost or must be retransmitted. For serial data transmission locally or in a network, the **Xon/Xoff** protocol can be used. For **modem** connections, either Xon/Xoff or CTS/RTS (Clear to Send/Ready to Send) commands can be used to control data flow.

In a network, flow control can also be applied by refusing additional device connections until the flow of traffic has subsided.

flowchart

A flowchart is a formalized graphic representation of a program logic sequence, work or manufacturing process, organization chart, or similar formalized structure. In computer programming, flowcharts were formerly used to describe each processing path in a program (the main program and various subroutines that could be branched to). Programmers were admonished to always flowchart their logic rather than carry it in their heads. With the advent of object-oriented programming (OOP) and visual development tools, the traditional program flowchart is much less frequently seen. However, there are new flowcharts that can be used for the data or class modeling that is used in object-oriented programming.

Traditional program flowcharting involves the use of simple geometric symbols to represent the beginning or end of a program (an oval), a process (a rectangle), a decision (a diamond), or an I/O process (a parallelogram). These symbols are defined in ANSI x 3.5 and ISO 1028.

flux

Flux is the presence of a force field in a specified physical medium, or the flow of energy through a surface. In electronics, the term applies to any **electrostatic field** and any **magnetic field**. Flux is depicted as "lines" in a plane that contains or intersects electric charge poles or magnetic poles. Three examples of *flux lines* are shown in the illustration.

Drawing A shows the geometric orientation of the lines of flux in the vicinity of an electrically charged object. The intensity of the field is inversely proportional to the

separation between the lines of flux. The *flux density*, and hence the electrostatic field strength, decreases as the distance from the charged object increases. Electrostatic flux density is inversely proportional to the distance from the charge center.

Drawing B illustrates flux lines surrounding a current-carrying conductor as they appear in a plane perpendicular to the conductor. As with the flux surrounding an electrically charged object, the separation between the flux lines increases as the distance from the conductor increases. Magnetic flux density is inversely proportional to the distance from a current-carrying conductor, as measured in a plane perpendicular to the conductor.

Drawing C shows the general orientation of the lines of flux of an electrostatic field between two oppositely charged poles in a plane containing the centers of both poles. In a magnetic field between opposite poles, the flux lines have the same general shape and orientation, so this drawing also applies to that situation. The flux density is greatest near the poles. The flux density is considerable along and near a line connecting the poles. As the distance from the line connecting the poles increases, the flux density decreases.

Flux lines are intangible; they cannot be seen. But they can be observed indirectly, and they produce demonstrable effects. If you place iron filings on a sheet of paper and place the paper on a magnet so both magnetic poles are near the paper, the filings line up in a pattern resembling illustration C. This demonstration is common in school science classes.

See “frequency modulation”

FMP

See “FileMaker”

fnord

Certain words are intended to be undefinable and “fnord” is one of them. First used in Robert Anton Wilson’ trilogy, *The Illuminati Papers*, fnord has developed a group of devotees that meet at certain pages in **cyberspace** to celebrate the word’s sense of the apparent but indefinite. The editors of whatis.com have spent far too much chasing the meaning of this elusive term, and this is what we are left with:

- Fnord is the space between the pixels on your screen.
- Fnord is the “ooo” in varoom of race cars.
- Fnord is the smallest number greater than zero.
- Fnord keeps a spare eyebrow in his pocket.

In Wilson’s trilogy (based on reports from users), truth is revealed to those who know where to look. The enlightened can see *fnord* in the empty spaces between unjustified columns of text in newspapers and magazines. Called sticky spots, these spaces are not really blank, but contain fnord, visible only to those privy to heavily guarded secrets and occult powers. Fans of the novel began using the word as a private joke and the concept spread to many who had never read the book but had no trouble discovering new places where *fnord* must clearly exist.

folder

In the Windows, Macintosh, and some other operating systems, a folder is a named collection of related **files** that can be retrieved, moved, and otherwise manipulated as one entity. **Mainframe** operating systems such as **OS/390** and most **UNIX**-based operating systems use the term **directory** rather than folder.

font

A font is a set of printable or displayable **text characters** in a specific style and size. The type design for a set of fonts is the **typeface** and variations of this design form the *typeface family*. Thus, Helvetica is a typeface family, Helvetica italic is a typeface, and Helvetica italic 10-point is a font. In practice, *font* and *typeface* are often used without much precision, sometimes interchangeably.

An *outline font* is a software typeface that can generate a scalable range of font sizes. A **bitmap font** is a digital representation of a font that is already fixed in size or a limited set of sizes. The two most popular outline font software programs on today’s computers are TrueType and Adobe’s Type 1. TrueType fonts come with both Windows and Macintosh operating systems. However, Type 1 is a standard outline font (ISO 9541). Both TrueType and Type 1 fonts can be used by Adobe’s PostScript printers (although Adobe says that Type 1 fonts makes fuller use of the PostScript language).

Independent developers and graphic designers create new typefaces for both TrueType and Type 1. Adobe states that there are over 30,000 Type 1 fonts available. Fonts (in addition to those that come with your computer) can be purchased as individual typeface families or in typeface collections.

foo

Just as economists sometimes use the term “widget” as the ultimate substitute for “something” that is being measured, programmers tend to use the term “foo” (pronounced FOO) as a universal substitute for something real when discussing ideas or presenting examples. Suppose you are defining a **template** for any group of programmers to follow when creating a new user command, you might specify that the **syntax** for the command should be in the form:

Command foo (arg1, arg2)

where the “foo” would mean “the name you give to this command.” In other words, “foo” is a nonsense kind of placeholder for some value that will be provided when using this template to define a real command. (And the “arg1” and “arg2” are arguments or information you would define that would be passed along with the command.) Because “foo” has no rational meaning of its own and because “foo” is conventionally used as such a placeholder, the idea will be clear to any programmer.

Foo or any such word used this way is formally known as a *metasyntactic variable*. Eric Raymond, probably the world’s greatest authority on foo and other metasyntactic variables, also lists qux, waldo, fred, xyzy, and thud among others that are occasionally used. Although foo is the **canonical** metasyntactic variable, Raymond notes that cultures outside the United States have their own preferences. Fred, Barney,

and wombat seem common in the U.K. Toto, tata, titi, and tutu reportedly are used by the French. Blarg and wibble are used in New Zealand.

The origin of foo seems wrapped in the mists of time, but Raymond observes (and we remember) that in Bill Holman's comic strip of the 1930-50 era, Smokey Stover, the letters "FOO" commonly appeared, unexplained and as a kind of running gag, on license plates, in picture frames, and on the backs of sandwich board signs.

foot-pound-second system of units

The foot-pound-second (fps) system of units is a scheme for measuring dimensional and material quantities. The fundamental units are the foot for length, the pound for weight, and the second for time.

The fps system has two variants, known as the American version and the Imperial version. Neither scheme is often used by scientists nowadays; the International System of Units (SI) is preferred. However, fps units are used to some extent by the general public, especially in the U.S.

Foot

One foot (1 ft) represents a length of 12 inches. The inch was originally defined as the length of three typical barleycorns laid end-to-end. A foot was also approximately equal to three hand widths or $\frac{2}{3}$ of a cubit (the distance from an average person's elbow to the tips of the fingers). Nowadays, a foot is considered to be 0.3048 meter, where the **meter** is the fundamental unit of displacement in the **metric system** and International System of Units (SI).

Pound

One pound (1 lb) is the force that produces an acceleration of 32.1740 feet per second squared (32.1740 ft/sec²) when applied against a known standard mass. The acceleration of 32.1740 ft/sec² is approximately the value of the earth's gravitational acceleration at 45 degrees north latitude.

Second

One second (1 s or 1 sec) is the time that elapses during 9.192631770×10^9 cycles of the radiation produced by the transition between two levels of Cesium 133. It is also 1/86,400 of a mean solar day. (There are 60 seconds in a minute, 60 minutes in an hour, and 24 hours in a day; $60 \times 60 \times 24 = 86,400$.)

footprint

In information technology, a footprint is the amount of space a particular unit of hardware or software occupies. Marketing brochures frequently state that a new hardware control unit or desktop display has a "smaller footprint," meaning that it occupies less space in the closet or on your desk. More recently, the term is used to describe microcomponents that take less space inside a computer and software that occupies less space in **memory** (whether **random access memory** or **read-only memory**).

footprinting

1) In the study of DNA, footprinting is the method used to identify the nucleic acid sequence that binds with proteins.

2) In computers, footprinting is the process of accumulating data regarding a specific network environment, usually for the purpose of finding ways to intrude into the environment. Footprinting can reveal system vulnerabilities and improve the ease with which they can be exploited.

Footprinting begins by determining the location and objective of an intrusion. Once this is known, specific information about the organization is gathered using non-intrusive methods. For example, the organization's own Web page may provide a personnel directory or employee bios, which may prove useful if the hacker needs to use **social engineering** to reach the objective. Conducting a whois query on the Web provides the domain names and associated networks related to a specific organization.

Other information obtained may include learning the Internet technologies being used; the operating system and hardware being used; IP addresses; e-mail addresses and phone numbers; and policies and procedures.

for your information

This term is included in our list of chat term and other **chat abbreviations**.

FYI (pronounced EFF-WAI-AI) is an abbreviation for "For your information," and is often used in forwarding **e-mail** or printed material to colleagues or friends. It usually means that information is simply being shared and that no immediate action is required or expected.

force

Force is an action that causes a free object with nonzero, finite mass to accelerate, relative to a non-accelerating frame of reference. Examples of force include the thrust of a rocket engine, the impetus that causes a car to speed up when you step on the accelerator, and the pull of gravity on your body. Force is the effect that produces the phenomenon of weight for objects with nonzero, finite **mass**.

The standard unit of force is the **newton**. One newton is equivalent to one kilogram-meter per second squared ($\text{kg} \cdot \text{m}/\text{s}^2$ or $\text{kg} \cdot \text{m} \cdot \text{s}^{-2}$). Alternatively, the **dyne** is sometimes used to express force; one dyne is equal to one gram-centimeter per second squared ($\text{g} \cdot \text{cm}/\text{s}^2$ or $\text{g} \cdot \text{cm} \cdot \text{s}^{-2}$). To convert from newtons to dynes, multiply by 100,000 (10^5). Conversely, multiply by 0.00001 (10^{-5}).

Force is defined in mechanical terms, but it can result from the action of electric fields, magnetic fields, thermal heating, particle bombardment, and various other phenomena. In all cases, force has the property of imparting acceleration to particles or objects. If an object is anchored so it cannot move, a force against it produces pressure.

Also see **impulse**, **mass**, **newton**, **pressure**, **weight**, **SI** (International System of Units), and **Table of Physical Units**.

form factor

1) In computers, the form factor (sometimes hyphenated as form-factor) is the size, configuration, or physical arrangement of a computer hardware object. The term is commonly used in describing the size and/or arrangement of a computer case or chassis or one of its internal components such as a *daughterboard*. If you see the term applied to software or programming, it will usually mean the size of the program or the amount of memory required to run the program effectively. When used to refer to the size of a free-standing computer or other device, it's close in meaning to **footprint**.

2) In electric motor terminology, a form factor is the amount of rectified current emitted from a direct current (DC) power source and is expressed as a ratio of the root-mean square (rms) value of the current to the average (av) current or I_{rms}/I_{av} . If the form factor differs much from pure non-pulsating DC (a value of 1.0), it indicates the possibility that motor and brush life will be shorter.

format

1) A format (noun, pronounced FOHR-mat) is a pre-established layout for data. **Programs** accept data as input in a certain format, process it, and provide it as output in the same or another format. All data is stored in some format with the expectation that it will be processed by a program that knows how to handle that format. Generically, data formats tend to fall into **bitmaps** (strings of 0s and 1s) that describe images or sound patterns (or both), text formats (in which usually each **byte** value is mapped to a **character**), and numeric data formats (used by spreadsheet and other **database** programs).

Hard disk and other storage devices are also said to be formatted when their space has been organized and divided into pieces that can be controlled for convenient storage and access. For example, a hard disk may be formatted into areas called sectors, tracks, and clusters.

2) To format (verb) a document or file for printing or displaying is to add the necessary information to it so that the output device will know how to present the output.

3) To format (verb) a hard disk or diskette is to set up the space divisions on the medium and initiate a space allocation table that will know exactly how to reach each bit of data that may be stored there later.

Fortezza

Fortezza, Italian for "fortress," is a family of security products trademarked by the US government's National Security Agency. Fortezza-enabled security is popular with government agencies, especially the military. The Fortezza

crypto card (similar to a **PC Card**) works in PCs loaded with Talisman software, which **encrypts** every file on the computer. Then, only a user with the correct Fortezza crypto card and password can gain access to the encrypted data.

Currently, the main use of Fortezza is for encrypting e-mail, but Fortezza security is also included in digital cellular telephones, Web browsers, and databases. The technology hasn't gained widespread acceptance in the corporate world, primarily because many businesses simply don't trust government-developed technology. However, the latest version of Microsoft's Windows 2000 Web server, the Internet Information Server (**IIS**), supports Fortezza.

Forth

Forth is a high-level programming language that works like reverse Polish notation (RPN) on a calculator. It differs from typical programming languages, like **C** and **FORTRAN**, because it is interactive. Using Forth, a user doesn't need to recompile a program to add new functionality; the user defines a new command and it is available right away.

Forth has one of the simplest syntaxes of any computer language. The syntax can be stated as: Forth code is a bunch of words with spaces between them. Each word is equivalent to a function or subroutine in a language like **C**. Functions are executed in the order they appear in the code. The following statement is an example that could appear in a Forth program: WAKE.UP EAT.BREAKFAST WORK EAT.DINNER PLAY SLEEP. The dots between WAKE and UP and the other words simply connect the two words to make one. Forth word names can have any combination of letters, numbers, or punctuation.

FORTRAN

FORTRAN (FORmula TRANslation) is a third-generation (3GL) programming language that was designed for use by engineers, mathematicians, and other users and creators of scientific algorithms. It has a very succinct and spartan syntax. Today, the **C** language has largely displaced FORTRAN.

forward carbon copy

See "Fcc"

forward compatible

Also see **backward compatible**.

Forward compatible describes a system that is designed in such a way that it fits with planned future versions of itself. Forward compatible usually implies that dependent systems, such as application programs developed for a specific operating system, will work in a satisfactory way in future as well as in the current, forward compatible system.

Forward DNS lookup

Forward DNS lookup is using an Internet **domain name** to find an **IP address**. Reverse DNS lookup is using an Internet IP address to find a domain name. When you enter the address for a Web site at your browser (the address is formally called the Uniform Resource Locator, or **URL**), the address is transmitted to a nearby **router** which does a forward DNS lookup in a routing table to locate the IP address. Forward **DNS** (which stands for domain name system) lookup is the more common lookup since most users think in terms of domain names rather than IP addresses. However, occasionally you may see a Web page with a URL in which the domain name part is expressed as an IP address (sometimes called a **dot address**) and want to be able to see its domain name. An Internet facility that lets you do either forward or reverse DNS lookup yourself is called **nslookup**. It comes with some operating systems or you can download the program and install it in your computer.

FPGA

See "field-programmable gate array"

FPM DRAM

Prior to newer forms of DRAM, FPM DRAM (Fast Page Mode DRAM) was the most common kind of dynamic RAM in personal computers. *Page mode* DRAM essentially accesses a row of RAM without having to continually respecify the row. A row access strobe (**RAS**) signal is kept active while the column access strobe (**CAS**) signal changes to read a sequence of contiguous memory cells. This reduces access time and lowers power requirements. Clock timings for FPM DRAM are typically 6-3-3-3 (meaning 3 clock cycles for access setup, and 3 clock cycles for the first and each of three successive accesses based on the initial setup).

FpML

Financial Products Markup Language (FpML) is a business information exchange standard based on Extensible Markup Language (**XML**) that enables **business-to-business** over-the-counter (OTC) financial derivative transactions using the **Internet**. FpML is used between participating companies for communicating OTC transaction details, within a company for the purpose of sharing OTC transaction information, and between a participating company and an outside firm offering a service related to the OTC transaction. FpML is freely licensed and, because it is independent of the software or hardware used by participating companies, ensures **interoperability**. FpML focuses on interest rate swaps and Forward Rate Agreements (FRA) but will eventually be used for all aspects of OTC transactions.

OTC contracts shared between two companies are highly customized based on the needs of the parties involved. For this reason, prior to the arrival of the Internet and XML, it

was not feasible to efficiently carry out the OTC contract process online. Today, companies can electronically structure and negotiate the terms of an OTC contract, execute and confirm the contract, communicate settlement details, and analyze risks using FpML.

Chase Manhattan Bank has reviewed and adopted FpML for their OTC Interest Rate Derivative applications. Fuji Capital Markets Corporation used the FpML definition to design their XML-based FRA confirmation prototype. And J.P. Morgan developed an FpML interest rate swap prototype application. Organizations participating in the development and application of FpML include Bank of America, Citigroup, Deutsche Bank, IBM, PricewaterhouseCoopers, J.P. Morgan, Reuters, and UBS Warburg.

See "floating point unit"

FQDN

See "fully-qualified domain name"

fractional T-1

A fractional T-1 or T-3 line is a T-1 or T-3 digital phone line in the North American **T-carrier system** that is leased to a customer at a fraction of its data-carrying capacity and at a correspondingly lower cost. A T-1 line contains 24 channels, each with a data transfer capacity of 64 **Kbps**. The customer can rent some number of the 24 channels. The transmission method and speed of transfer remain the same. Overhead bits and framing are still used, but the unrented channels simply contain no data.

T-3 lines (which offer 672 64 Kbps channels) are also sometimes offered as a fractional service. T-1 and fractional T-1 service are sometimes advertised as "point-to-point" service (from the customer to the service provider).

FRAD

A FRAD (frame relay access device; also sometimes referred to as a frame relay assembler/disassembler) is a box that encapsulates (puts **frame relay** header and trailer information on) outgoing data **packets** and decapsulates (removes frame relay headers and trailers from) incoming packets. Frame relay is a system in which data (in the form of packets) from different protocols such as **Ethernet**, X.25, and the Internet Protocol (**IP**) is collected into "frames" or larger units of transmission that are delivered in burst-like mode over a switched connection that is, however, a "permanent virtual circuit" (PVC). A PVC ensures that packets always arrive in the right order so that they can be

reassembled successfully. Since frame relay does not take responsibility for error detection, the FRAD sometimes includes error detection.

The FRAD is a box, usually close to the user, that provides the interface between the user and a network that uses frame relay. The FRAD is sometimes included as part of a **router**.

FRAM

FRAM (ferroelectric RAM) is **random access memory** that combines the fast read and write access of dynamic RAM (**DRAM**)—the most common kind of personal computer memory—with the ability to retain data when power is turned off (as do other non-volatile memory devices such as **ROM** and **flash memory**). Because FRAM is not as dense (can not store as much data in the same space) as DRAM and **SRAM**, it is not likely to replace these technologies. However, because it is fast memory with a very low power requirement, it is expected to have many applications in small consumer devices such as personal digital assistants (**PDA**s), handheld phones, power meters, and **smart cards**, and in security systems. FRAM is faster than flash memory. It is also expected to replace **EEPROM** and SRAM for some applications and to become a key component in future **wireless** products.

In spite of its name, ferroelectric RAM does not contain iron. Today's FRAM uses lead zirconate titanate (PZT); other materials are being considered. The main developer of FRAM is Ramtron International.

frame

See **frames** for the use of multiple Web pages on a single display screen.

1) In telecommunications, a frame is **data** that is transmitted between network points as a unit complete with addressing and necessary **protocol** control information. A frame is usually transmitted **serial bit** by bit and contains a header field and a trailer field that "frame" the data. (Some control frames contain no data.)

Here is a simple representation of a frame, based on the frame used in the **frame relay** access standard:

———Header———	———Trailer———			
Flag	Address	Information	Frame	Flag
(01111110)	field	(data)	check	(01111110)
		(0-4096	sequence	
		bytes)		

In the figure above, the flag and address fields constitute the header. The frame check sequence and second flag fields constitute the trailer. The information or data in the frame may contain another encapsulated frame that is used in a higher-level or different protocol. In fact, a frame relay frame typically carries data that has been framed by an earlier protocol program.

2) In time-division multiplexing (**TDM**), a frame is a complete cycle of events within the time division period.

3) In film and video recording and playback, a frame is a single image in a sequence of images that are recorded and played back.

4) In computer video display technology, a frame is the image that is sent to the display image rendering devices. It is continuously updated or refreshed from a *frame buffer*, a highly accessible part of video RAM.

5) In artificial intelligence (**AI**) applications, a frame is a set of data with information about a particular object, process, or image. An example is the iris-print visual recognition system used to identify users of certain bank automated teller machines. This system compares the frame of data for a potential user with the frames in its database of authorized users.

frame rate

In motion pictures, television, and in computer video displays, the frame rate is the number of frames or images that are projected or displayed per second. Frame rates are used in synchronizing **audio** and pictures, whether film, television, or video. In motion pictures and television, the frame rates are standardized by the Society of Motion Picture and Television Editors (SMPTE). SMPTE Time Code frame rates of 24, 25 and 30 frames per second are common, each having uses in different portions of the industry. The professional frame rate for motion pictures is 24 frames per second and, for television, 30 frames per second (in the U.S.).

In computer video streams, the frame rate describes playback rates for AVI and QuickTime movies. The video playback rate for an AVI or QuickTime movie directly relates to the perceived smoothness of its playback. The higher the number of frames playing per second, the smoother the video playback appears to the user. Lower rates result in a choppy playback. (As a reference point, film uses 24 frames per second to allow the viewer to perceive smooth playback.) Several factors affect the actual frame rate you get on your computer. For example, your PC **processor** or graphics hardware may only be capable of playing 10–15 frames per second without acceleration.

In developing motion pictures, television, and video, frame rate information is used as a reference for audio signals. The recorded signal includes information about location in time using a 24-hour clock, and individual frame numbers. This signal is used to synchronize multiple audio and video machines during the recording and editing process. Using a master synchronizing device, the operator can issue location commands from a central machine and have all slaved machines follow the master.

frame relay

Frame relay is a telecommunication service designed for cost-efficient data transmission for intermittent traffic between local area networks (**LAN**s) and between endpoints in a wide area network (**WAN**). Frame relay puts data

in a variable-size unit called a **frame** and leaves any necessary error correction (retransmission of data) up to the end-points, which speeds up overall data transmission. For most services, the network provides a permanent virtual circuit (**PVC**), which means that the customer sees a continuous, dedicated connection without having to pay for a full-time leased line, while the service provider figures out the route each frame travels to its destination and can charge based on usage. An enterprise can select a level of service quality—prioritizing some frames and making others less important. Frame relay is offered by a number of service providers, including AT&T. Frame relay is provided on **fractional T-1** or full **T-carrier system** carriers. Frame relay complements and provides a mid-range service between **ISDN**, which offers **bandwidth** at 128 Kbps, and **Asynchronous Transfer Mode (ATM)**, which operates in somewhat similar fashion to frame relay but at speeds from 155.520 Mbps or 622.080 Mbps.

Frame relay is based on the older **X.25** packet-switching technology which was designed for transmitting **analog** data such as voice conversations. Unlike X.25 which was designed for analog signals, frame relay is a **fast packet technology**, which means that the protocol does not attempt to correct errors. When an error is detected in a frame, it is simply “dropped” (thrown away). The end points are responsible for detecting and retransmitting dropped frames. (However, the incidence of error in digital networks is extraordinarily small relative to analog networks.)

Frame relay is often used to connect local area networks with major backbones as well as on public wide area networks and also in private network environments with leased lines over T-1 lines. It requires a dedicated connection during the transmission period. It's not ideally suited for voice or video transmission, which requires a steady flow of transmissions. However, under certain circumstances, it is used for voice and video transmission.

Frame relay relays packets at the **Data Link layer** of the Open Systems Interconnection (**OSI**) model rather than at the **Network layer**. A frame can incorporate packets from different protocols such as **Ethernet** and **X.25**. It is variable in size and can be as large as a thousand bytes or more.

frame relay access device

See “FRAD”

frames

See **frame** for additional meanings.

In creating a Web site, frames is the use of multiple, independently controllable sections on a Web presentation. This effect is achieved by building each section as a separate **HTML** file and having one “master” **HTML** file identify all of the sections. When a user requests a Web page that uses frames, the address requested is actually that of the “master” file that defines the frames; the result of the request is that

multiple **HTML** files are returned, one for each visual section. Links in one frame can request another file that will appear in another (or the same) frame. A typical use of frames is to have one frame containing a selection menu in one frame and another frame that contains the space where the selected (linked to) files will appear.

Frames, originally created by Netscape as an **HTML** extension and now part of the **HTML 4.0**, specification are defined with **HTML FRAMESET** and **FRAME** tags. Sites that use frames need to create an alternative scheme of pages for requests from browsers that don't support them and possibly for users that prefer a non-frames version.

Free Software Foundation

The Free Software Foundation (FSF) was founded in 1983 along with its demonstration **GNU** project. Richard Stallman, an MIT professor, had worked as a student on projects where software was freely exchanged without copying or modifying stipulations. Why, he asked himself and others, should software users be prohibited from copying it for friends, looking at the source code and copying it, and redistributing the results? Taking this idea to the group level, Stallman and others created the FSF and set out to demonstrate that an entire **operating system** could be developed and shared freely. The result was the **UNIX**-like **GNU**, which, in August 1996, became complete by adding a **kernel**.

The “free” does not mean at no charge. The Free Software Foundation does charge an initial distribution price for **GNU**. “Free” refers to the use the person who acquires the software has with it. The Free Software Foundation believes that individuals and society would benefit from, and moreover have the right to study a program's source code to discover how it works, to make changes that enhance the program in some way, and to redistribute and even to sell improved versions to others as long as they in turn make their software free of reuse restrictions.

freemail

Freemail is a service that provides free **e-mail** delivery to anyone in exchange for exposure to advertising on the site where you request your e-mail and, in some cases, for some personal information. Assuming you currently get e-mail as part of your **Web browser**, the advantage to freemail is that you can log in to the freemail provider from anyone's Internet access and don't have to use your own **Internet service provider** or remember its phone number. If you don't have your own Web account, you can use someone else's computer but still get your own e-mail from the freemail Web site. For example, college students who don't have their own computers or Internet access can register for freemail and send and receive e-mail at their nearest **cybercafe**.

Unlike your regular e-mail interface which is a separate program (although it comes integrated with the popular Web browsers), most freemail providers require using a forms interface with a Web site that is more time-consuming than programs designed expressly for e-mail. In general, freemail is simpler but offers fewer services than when using the e-mail program with your browser and being connected to your own Internet access provider.

Among the most popular freemail providers are Hotmail, apparently the most popular and according to a recent RelevantKnowledge survey, the 13th most visited site on the Web; Rocketmail, also very popular; and Juno, one of the first freemail providers. Juno requires you to use its own software interface rather than a Web browser.

freeware

Freeware is programming that is offered at no cost. However, it is copyrighted so that you can't incorporate its programming into anything you may be developing. The least restrictive "no-cost" programs are uncopyrighted programs that are in the public domain. These include a number of small UNIX programs. When reusing public domain software in your own programs, it's good to know the history of the program so that you can be sure it really is in the public domain.

Also see **liteware**, **postcardware**, and **shareware**.

free-space optics

Free-space optics (FSO), also called free-space photonics (FSP), refers to the transmission of modulated visible or infrared (IR) beams through the atmosphere to obtain **broadband** communications. **Laser** beams are generally used, although non-lasing sources such as light-emitting diodes (LEDs) or IR-emitting diodes (IREDS) will serve the purpose.

The theory of FSO is essentially the same as that for **fiber optic** transmission. The difference is that the energy beam is collimated and sent through clear air or space from the source to the destination, rather than guided through an optical fiber. If the energy source does not produce a sufficiently parallel beam to travel the required distance, collimation can be done with lenses. At the source, the visible or IR energy is modulated with the data to be transmitted. At the destination, the beam is intercepted by a photodetector, the data is extracted from the visible or IR beam (demodulated), and the resulting signal is amplified and sent to the hardware.

FSO systems can function over distances of several kilometers. As long as there is a clear line of sight between the source and the destination, communication is theoretically possible. Even if there is no direct line of sight, strategically positioned mirrors can be used to reflect

the energy. The beams can pass through glass windows with little or no attenuation (as long as the windows are kept clean!).

Although FSO systems can be a good solution for some broadband networking needs, there are limitations. Most significant is the fact that rain, dust, snow, fog, or smog can block the transmission path and shut down the network.

free-space photonics

See "free-space optics"

frequency

For an oscillating or varying **current**, frequency is the number of complete cycles per second in alternating current direction. The standard unit of frequency is the **hertz**, abbreviated Hz. If a current completes one cycle per second, then the frequency is 1 Hz; 60 cycles per second equals 60 Hz (the standard alternating-current utility frequency in some countries).

Larger units of frequency include the **kilohertz** (kHz) representing thousands (1,000's) of cycles per second, the **megahertz** (MHz) representing millions (1,000,000's) of cycles per second, and the **gigahertz** (GHz) representing billions (1,000,000,000's) of cycles per second. Occasionally the **terahertz** (THz) is used; 1 THz = 1,000,000,000,000 cycles per second. Note that these prefixes represent specific powers of 10, in contrast to the prefixes for multiples of bytes, which represent specific powers of 2.

Computer clock speed is generally specified in megahertz and, more recently, in gigahertz.

Frequency is important in **wireless** communications, where the frequency of a signal is mathematically related to the **wavelength**. If f is the frequency of an **electromagnetic field** in free space as measured in megahertz, and w is the wavelength as measured in meters, then

$$w = 300/f$$

and conversely

$$f = 300/w$$

Also see the definitions of **signal** and **electromagnetic radiation spectrum**.

frequency division multiple access

See "FDMA"

frequency modulation

Also see **modulation** and frequency-shift keying (FSK).

Frequency modulation (FM) is a method of impressing data onto an alternating-current (AC) **wave** by varying the instantaneous **frequency** of the wave. This scheme can be used with **analog** or **digital** data.

In analog FM, the frequency of the AC **signal** wave, also called the *carrier*, varies in a continuous manner. Thus, there are infinitely many possible carrier frequencies. In *narrowband FM*, commonly used in two-way **wireless** communications, the instantaneous carrier frequency varies by up to 5 kilohertz (kHz, where 1 kHz = 1000 **hertz** or alternating cycles per second) above and below the frequency of the carrier with no modulation. In *wideband FM*, used in wireless broadcasting, the instantaneous frequency varies by up to several megahertz (MHz, where 1 MHz = 1,000,000 Hz). When the instantaneous input wave has positive **polarity**, the carrier frequency shifts in one direction; when the instantaneous input wave has negative polarity, the carrier frequency shifts in the opposite direction. At every instant in time, the extent of carrier-frequency shift (the *deviation*) is directly proportional to the extent to which the signal amplitude is positive or negative.

In digital FM, the carrier frequency shifts abruptly, rather than varying continuously. The number of possible carrier frequency states is usually a power of 2. If there are only two possible frequency states, the mode is called frequency-shift keying (**FSK**). In more complex modes, there can be four, eight, or more different frequency states. Each specific carrier frequency represents a specific digital input data state.

Frequency modulation is similar in practice to phase modulation (**PM**). When the instantaneous frequency of a carrier is varied, the instantaneous phase changes as well. The converse also holds: When the instantaneous phase is varied, the instantaneous frequency changes. But FM and PM are not exactly equivalent, especially in analog applications. When an FM receiver is used to demodulate a PM signal, or when an FM signal is intercepted by a receiver designed for PM, the audio is distorted. This is because the relationship between frequency and phase variations is not linear; that is, frequency and phase do not vary in direct proportion.

frequency-division multiplexing

Frequency-division multiplexing (FDM) is a scheme in which numerous signals are combined for transmission on a single communications line or channel. Each signal is assigned a different frequency (subchannel) within the main channel.

A typical **analog** Internet connection via a **twisted pair** telephone line requires approximately three kilohertz (3 kHz) of **bandwidth** for accurate and reliable data transfer. Twisted-pair lines are common in households and small businesses. But major telephone cables, operating between large businesses, government agencies, and municipalities, are capable of much larger bandwidths.

Suppose a long-distance cable is available with a bandwidth allotment of three megahertz (3 **MHz**). This is 3,000 kHz, so in theory, it is possible to place 1,000 signals, each 3 kHz wide, into the long-distance channel. The circuit that does

this is known as a **multiplexer**. It accepts the input from each individual end user, and generates a signal on a different frequency for each of the inputs. This results in a high-bandwidth, complex signal containing data from all the end users. At the other end of the long-distance cable, the individual signals are separated out by means of a circuit called a demultiplexer, and routed to the proper end users. A two-way communications circuit requires a multiplexer/demultiplexer at each end of the long-distance, high-bandwidth cable.

When FDM is used in a communications network, each input signal is sent and received at maximum speed at all times. This is its chief asset. However, if many signals must be sent along a single long-distance line, the necessary bandwidth is large, and careful engineering is required to ensure that the system will perform properly. In some systems, a different scheme, known as **time-division multiplexing**, is used instead.

frequency-hopping spread spectrum

Frequency hopping is one of two basic **modulation** techniques used in **spread spectrum signal** transmission. It is the repeated switching of frequencies during radio transmission, often to minimize the effectiveness of “electronic warfare”—that is, the unauthorized interception or jamming of telecommunications. It also is known as frequency hopping-code division multiple access (**FH-CDMA**).

Spread spectrum modulation techniques have become more common in recent years. Spread spectrum enables a signal to be transmitted across a **frequency band** that is much wider than the minimum **bandwidth** required by the information signal. The transmitter “spreads” the energy, originally concentrated in **narrowband**, across a number of frequency band channels on a wider **electromagnetic spectrum**. Benefits include improved privacy, decreased narrowband interference, and increased signal capacity.

In an FH-CDMA system, a transmitter “hops” between available frequencies according to a specified **algorithm**, which can be either random or preplanned. The transmitter operates in synchronization with a receiver, which remains tuned to the same center frequency as the transmitter. A short burst of data is transmitted on a narrowband. Then, the transmitter tunes to another frequency and transmits again. The receiver thus is capable of hopping its frequency over a given bandwidth several times a second, transmitting on one frequency for a certain period of time, then hopping to another frequency and transmitting again. Frequency hopping requires a much wider bandwidth than is needed to transmit the same information using only one carrier frequency.

The spread spectrum approach that is an alternative to FH-CDMA is direct sequence code division multiple access (**DS-CDMA**), which chops the data into small pieces and spreads them across the frequency domain. FH-CDMA devices use

less power and are generally cheaper, but the performance of DS-CDMA systems is usually better and more reliable. The biggest advantage of frequency hopping lies in the coexistence of several access points in the same area, something not possible with direct sequence.

Certain rules govern how frequency-hopping devices are used. In North America, the Industrial, Scientific, and Medical (ISM) waveband is divided into 75 hopping channels, with power transmission not to exceed 1 watt on each **channel**. These restrictions ensure that a single device does not consume too much bandwidth or linger too long on a single frequency.

The Federal Communications Commission (FCC) has amended rules to allow frequency hopping spread spectrum systems in the unregulated 2.4 GHz band. The rule change is designed to allow wider bandwidths, thus enabling Internet devices to operate at higher speeds and fostering development of **wireless LANs** and wireless cable modems.

Movie star Hedy Lamarr is generally credited as co-originator of the idea of spread spectrum transmission. She and her pianist were issued a patent for the technique during World War II. They discovered the technique using a player piano to control the frequency hops, and envisioned it as a way to provide secure communications during wartime. The pair never made any money off the invention and their patent eventually expired. Sylvania introduced a similar concept in the 1950s and coined the term “spread spectrum.”

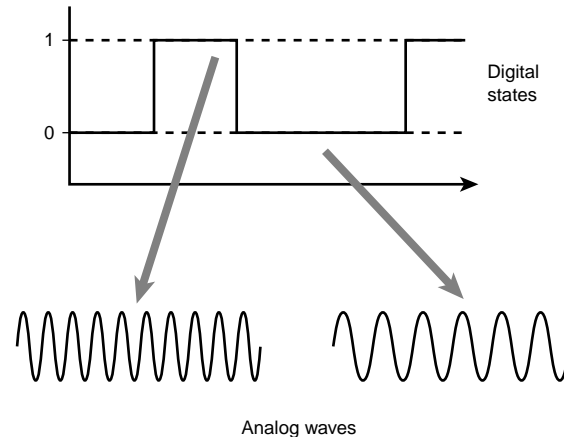

frequency-shift keying

See also phase-shift keying (PSK).

Frequency-shift keying (FSK) is a method of transmitting **digital** signals. The two **binary** states, logic 0 (low) and 1 (high), are each represented by an **analog waveform**. Logic 0 is represented by a wave at a specific **frequency**, and logic 1 is represented by a wave at a different frequency. A **modem** converts the binary data from a computer to FSK for transmission over telephone lines, cables, **optical fiber**, or wireless media. The modem also converts incoming FSK signals to digital low and high states, which the computer can “understand.”

The FSK mode was introduced for use with mechanical teleprinters in the mid-1900s. The standard speed of those machines was 45 **baud**, equivalent to about 45 bits per second. When personal computers became common and networks came into being, this signaling speed was tedious. Transmission of large text documents and programs took hours; image transfer was unknown. During the 1970s, engineers began to develop modems that ran at faster speeds, and the quest for ever-greater **bandwidth** has continued ever since. Today, a standard telephone modem operates at thousands of bits per second. Cable and wireless modems work at more than 1,000,000 bps (one megabit per

second or 1 Mbps), and optical fiber modems function at many Mbps. But the basic principle of FSK has not changed in more than half a century.

frequently-asked questions

The FAQ (pronounced FAK) or list of “frequently-asked questions” (and answers) has become a feature of the Internet. The FAQ seems to have originated in many of the **Usenet** groups as a way to acquaint new users with the rules. Today, there are thousands of FAQs on the World Wide Web.

To see the range and variety of topics for which FAQs have been written, go to Yahoo or any major **search engine**, and enter “faq” or “faqs” in the search entry box. To find a FAQ on a subject of interest (for example, hedgehogs), enter “faq and hedgehogs”(without the quotes). Also note that the number of subjects on which you will NOT find is FAQ is also large. The most useful FAQs are often found at a Web site you’ve discovered through other search approaches.

front-end

Front-end and back-end are terms used to characterize program interfaces and services relative to the initial user of these interfaces and services. (The “user” may be a human being or a program.) A “front-end” **application** is one that application users interact with directly. A “back-end” application or program serves indirectly in support of the front-end services, usually by being closer to the required resource or having the capability to communicate with the required resource. The back-end application may interact directly with the front-end or, perhaps more typically, is a program called from an intermediate program that mediates front-end and back-end activities.

For example, the Telephony Application Program Interface (TAPI) is sometimes referred to as a front-end interface for telephone services. A program’s TAPI requests are mapped

by Microsoft's TAPI Dynamic Link Library programs (an intermediate set of programs) to a "back-end" program or **driver** that makes the more detailed series of requests to the telephone hardware in the computer.

As another example, a front-end application might interface directly with users and forward requests to a remotely-located back-end program in another computer to get requested data or perform a requested service. Relative to the **client/server** computing model, a front-end is likely to be a client and a back-end to be a server.

frontside bus

See also: **backside bus**

In a personal computer with an Intel **processor chipset** that includes a Dual Independent Bus (DIB), the frontside **bus** is the data path and physical interface between the processor and the main memory (**RAM**).

FRR

See "fast retransmit and recovery"

FSB

See "frontside bus"

FSK

See "frequency-shift keying"

FSML

See "Financial Services Markup Language"

FSO

See "free-space optics"

FSP

On the Internet, an FSP (full-service provider) is an application service provider (**ASP**) that offers a wide range of Web-based information technology services to other companies—including the planning and creation of a Web presence, providing needed software applications, and **hosting** and maintaining the site. The FSP aims to consolidate and streamline a customer's Internet operations and to offer a single point of contact for an array of services.

FTP

See "File Transfer Protocol"

FTP cable

FTP (foil screened twisted pair) cable is a cable containing multiple pairs of copper wire enclosed in a sheath of aluminum foil. It's used in wiring systems in buildings or

other environments where heavy noise adjacent to the wire might cause interference. The foil provides insulation not afforded by **UTP** (unshielded twisted pair), the most common kind of structural wiring. The disadvantage of FTP is that it requires somewhat more care in "earthing" (grounding) than **UTP** and electrical impedances must be matched when connecting to **UTP**. Typically, FTP might be used in a factory setting and **UTP** in an office setting.

FTTC

See "fiber to the curb"

FUBAR

FUBAR is an acronym that originated in the military to stand for the words "f***ed up beyond all repair." This is often softened to "fouled up beyond all repair" in reference to hardware. The programming and documentation equivalent is "fouled up beyond all recognition." Sometimes the last word is "recovery" or "reconciliation" or "reason."

In a Virtual Address Extension (VAX), the acronym FUBAR has been adapted to refer to the words "failed UniBus address register." Some programmers apparently managed to sneak this by humorless higher-ups, and the term stuck.

F.U.B.A.R. International is the name of a film company founded in 1989 by several businessmen seeking adventure. They went on location to film natural disasters. Some of the disasters were artificially created, especially avalanches, which could be triggered by explosives. Company executives vacation in Vail, Colorado every year, and have become local celebrities. These days, F.U.B.A.R. International markets clothing and novelty items.

Because **foo**, an unrelated term, appears phonetically in FUBAR, programmers have taken to using both *foo* and **bar** as metasyntactic variables when two such variables are needed.

FUD

FUD (Fear, Uncertainty, and Doubt) is the term for any strategy intended to make a company's customers insecure about future product plans with the purpose of discouraging them from adopting competitors' products. For example, "You can try using X instead of our product, but you may lose all your data."

full-duplex

Full-duplex data transmission means that data can be transmitted in both directions on a signal carrier at the same time. For example, on a local area network with a technology that has full-duplex transmission, one workstation can be sending data on the line while another workstation is receiving data. Full-duplex transmission necessarily implies a bidirectional line (one that can move data in both directions).

full-service provider

See “FSP”

fully-qualified domain name

A fully-qualified domain name (FQDN) is that portion of an Internet Uniform Resource Locator (URL) that fully identifies the **server** program that an Internet request is addressed to. The FQDN includes the second-level **domain name** (such as “whatis.com”) and any other levels (for example, “www.whatis.com” or “www1.somesite.com”). The prefix “http://” added to the fully-qualified domain name completes the URL.

Fullerene

A Fullerene is a pure carbon molecule composed of at least 60 **atoms** of carbon. Because a Fullerene takes a shape similar to a soccer ball or a geodesic dome, it is sometimes referred to as a *buckyball* after the inventor of the geodesic dome, Buckminster Fuller, for whom the Fullerene is more formally named. Fullerenes are seen as promising components of future micro-electromechanical systems (MEMS) and in **nanotechnology**. Current work on the Fullerene is largely theoretical and experimental.

NASA, in co-operation with geochemist Lynn Becker from the University of Hawaii, has discovered naturally-occurring Fullerenes in ancient meteorites that hit the Earth. Recent research has suggested many uses for Fullerenes, including medical applications, superconductors, and fiber-optics.

function

In information technology, the term *function* (pronounced FUHNK-shun) has a number of meanings. It’s taken from the Latin “functio”—to perform.

- 1) In its most general use, a function is what a given **entity** does in being what it is.
- 2) In C language and other programming, a function is a named procedure that performs a distinct service. The language statement that requests the function is called a *function call*. Programming languages usually come with a **compiler** and a set of “canned” functions that a programmer can specify by writing language statements. These provided functions are sometimes referred to as *library routines*. Some functions are self-sufficient and can return results to the requesting program without help. Other functions need to make requests of the **operating system** in order to perform their work.
- 3) In mathematics, a function is an association between two sets of values in which each element of one set has one assigned element in the other set so that any element selected becomes the independent variable and its associated element is the dependent variable. Thus, in:

$$y = f(x)$$

y is said to be a function of x.

- 4) In a hardware device, a function is one complete physical movement that has a discernible consequence relative to the device’s purposes. In a printer, for example, this might be a carriage return or a line feed.

function key

On a computer **keyboard**, a function key is one of a sequence of special keys labeled “F1” or higher (usually up to “F12” on most keyboards) that can be assigned a specific use in order to save a user time. Some function keys have uses assigned by an operating system such as Windows and somewhat different uses when interacting with an application program. In some cases, the meaning of a function key can be described by the user to an application program.

A function key may be assigned a second use when it is pressed in combination with the shift key, ALT key, or Control key. A function key is sometimes considered to be a form of **hot key**.

functional programming

1) Functional programming is a style of programming that emphasizes the evaluation of expressions rather than the execution of commands. **Erlang programming language** is described as a functional programming language. Erlang avoids the use of global variables that can be used in common by multiple functions since changing such a variable in part of a program may have unexpected effects in another part.

2) In an earlier definition from the ITU-TS, functional programming is “a method for structuring programs mainly as sequences of possibly nested function procedure calls.” A function procedure is a relatively simple program that is called by other programs and derives and returns a value to the program that called it.

functional specification

A functional specification (or sometimes *functional specifications*) is a formal document used to describe in detail for software developers a product’s intended capabilities, appearance, and interactions with users. The functional specification is a kind of guideline and continuing reference point as the developers write the programming code. (At least one major product development group used a “Write the manual first” approach. Before the product existed, they wrote the user’s guide for a word processing system, then declared that the user’s guide was the functional specification. The developers were challenged to create a product that matched what the user’s guide described.) Typically, the functional specification for an application program with a series of interactive windows and dialogs with a user would show the visual appearance

of the user interface and describe each of the possible user input actions and the program response actions. A functional specification may also contain formal descriptions of user tasks, dependencies on other products, and usability criteria. Many companies have a guide for developers that describes what topics any product's functional specification should contain.

For a sense of where the functional specification fits into the development process, here are a typical series of steps in developing a software product:

- **Requirements.** This is a formal statement of what the product planners informed by their knowledge of the marketplace and specific input from existing or potential customers believe is needed for a new product or a new version of an existing product. Requirements are usually expressed in terms of narrative statements and in a relatively general way.
- **Objectives.** Objectives are written by product designers in response to the Requirements. They describe in a more specific way what the product will look like. Objectives may describe architectures, protocols, and standards to which the product will conform. *Measurable objectives* are those that set some criteria by which the end product can be judged. Measurability can be in terms of some index of customer satisfaction or in terms of capabilities and task times. Objectives must recognize time and resource constraints. The development schedule is often part or a corollary of the Objectives.
- **Functional specification.** The functional specification (usually *functional spec* or just *spec* for short) is the formal response to the objectives. It describes all *external* user and programming interfaces that the product must support.
- **Design change requests.** Throughout the development process, as the need for change to the functional specification is recognized, a formal change is described in a design change request.
- **Logic specification.** The structure of the programming (for example, major groups of code modules that support a similar function), individual code modules and their relationships, and the data parameters that they pass to each other may be described in a formal document called a logic specification. The logic specification describes *internal interfaces* and is for use only by the developers, testers, and, later, to some extent, the programmers that service the product and provide code fixes to the field.
- **User documentation.** In general, all of the preceding documents (except the logic specification) are used as source material for the technical manuals and online information (such as help pages) that are prepared for the product's users.

- **Test plan.** Most development groups have a formal test plan that describes test cases that will exercise the programming that is written. Testing is done at the module (or unit) level, at the component level, and at the system level in context with other products. This can be thought of as *alpha testing*. The plan may also allow for **beta test**. Some companies provide an early version of the product to a selected group of customers for testing in a "real world" situation.
- **The final product.** Ideally, the final product is a complete implementation of the functional specification and design change requests, some of which may result from formal testing and beta testing. The cycle is then repeated for the next version of the product, beginning with a new Requirements statement, which ideally uses feedback from customers about the current product to determine what customers need or want next.

Most software makers adhere to a formal development process similar to the one described above. The hardware development process is similar but includes some additional considerations for the outsourcing of parts and verification of the manufacturing process itself.

functionality

In information technology, *functionality* (from Latin *functio* meaning "to perform") is the sum or any aspect of what a product, such as a software application or computing device, can do for a user.

A product's functionality is used by marketers to identify product features and enables a user to have a set of capabilities. Functionality may or may not be easy to use.

Also see **function**.

Furby

Furby (pronounced FURR-bee) is the name of an electronic toy, five inches tall, that is covered with simulated fur, has big eyes and ears, a vocabulary of over 200 words, and a limited ability to react to its environment. Created by toy designer Dave Hampton and made by Tiger Electronics. Furby was designed to appeal to 7- to 9-year old girls but, based on early sales, the toy also appeals to anyone fascinated by technology. Each Furby contains **embedded systems programming** and six sensors so that it can:

- Dance, wiggle, and squirm in reaction to pokes and prods
- Talk in English and in its own language, Furbish
- Tell when the lights go out, when it's being petted, or when music is played—and react accordingly
- Hold a conversation with other Furbies (using **infrared transmission** signals)
- Catch another Furby's cold

Furby requires batteries and costs about \$30 US.

futzing

Futzing or “futzing around” is unstructured, playful, often experimental interaction between a human being and a computer, product, or any technology, sometimes but not always with a productive purpose in mind. Futzing can be pure play, learning by trying, or an attempt to achieve breakthrough insights. When someone says “Oh, I’m just futzing,” they may be just wasting time or they may be working on a hard problem or they may not even know.

fuzzy logic

Fuzzy logic is an approach to computing based on “degrees of truth” rather than the usual “true or false” (1 or 0) **Boolean** logic on which the modern computer is based. The idea of fuzzy logic was first advanced by Dr. Lotfi Zadeh of the University of California at Berkeley in the 1960s. Dr. Zadeh was working on the problem of computer understanding of natural language. Natural language (like most other activities in life and indeed the universe) is not easily translated into the absolute terms of 0 and 1. (Whether everything is ultimately describable in binary terms is a philosophical question worth pursuing, but in practice much data we might want to feed a computer is in some state in between and so, frequently, are the results of computing.)

Fuzzy logic includes 0 and 1 as extreme cases of truth (or “the state of matters” or “fact”) but also includes the various states of truth in between so that, for example, the result of a comparison between two things could be not “tall” or “short” but “.38 of tallness.”

Fuzzy logic seems closer to the way our brains work. We aggregate data and form a number of partial truths which we aggregate further into higher truths which in turn, when certain thresholds are exceeded, cause certain further results such as motor reaction. A similar kind of process is used in artificial computer **neural network** and expert systems.

It may help to see fuzzy logic as the way reasoning really works and binary or Boolean logic is simply a special case of it.

fuzzy number

See also **fuzzy logic**.

A fuzzy number is a quantity whose value is imprecise, rather than exact as is the case with “ordinary” (single-valued) numbers. Any fuzzy number can be thought of as a function whose domain is a specified **set** (usually the set of real numbers) and whose range is the span of non-negative real numbers between, and including, 0 and 1000. Each numerical value in the domain is assigned a specific “grade of membership” where 0 represents the smallest possible grade, and 1000 is the largest possible grade.

In many respects, fuzzy numbers depict the physical world more realistically than single-valued numbers. Suppose, for example, that you are driving along a highway where the speed limit is 55 miles an hour (mph). You try to hold your speed at exactly 55 mph, but your car lacks “cruise control,” so your speed varies from moment to moment. If you graph your instantaneous speed over a period of several minutes and then plot the result in rectangular coordinates, you will get a function that looks like one of the curves shown below.

The curve at the top represents a triangular fuzzy number; the curve in the middle shows a trapezoidal fuzzy number; the curve at the bottom illustrates a bell-shaped fuzzy number. These three functions, known as *membership functions*, are all convex (the grade starts at zero, rises to a maximum, and then declines to zero again as the domain increases). However, some fuzzy numbers have concave, irregular, or even chaotic membership functions. There is no

#

restriction on the shape of the membership curve, as long as each value in the domain corresponds to one and only one grade in the range, and the grade is never less than 0 nor more than 1000.

A

B

Fuzzy numbers are used in statistics, computer programming, engineering (especially communications), and experimental science. The concept takes into account the fact that all phenomena in the physical universe have a degree of inherent uncertainty.

G.lite

For more information, see **Digital Subscriber Line**.

G.Lite is the informal name for what is now a standard way to install Asymmetric Digital Subscriber Line (**ADSL**) service. Also known as Universal ADSL, G.Lite makes it possible to have Internet connections to home and business computers at up to 1.5 **Mbps** (millions of bits per second) over regular phone lines. Even at the lowest downstream rate generally offered of 384 **Kbps** (thousands of bits per second), G.Lite is about seven times faster than regular phone service with a **V.90** modem and three times faster than an Integrated Services Digital Network (**ISDN**) connection. Upstream speeds from the computer are at up to 128 Kbps. (Theoretical speeds for ADSL are much higher, but the data rates given here are what is realistically expected.)

With G.Lite, your computer's analog-to-digital **modem** is replaced with an "ADSL modem" and the transmission from the phone company is **digital** rather than the analog transmission of "plain old telephone service." G.Lite is also known as "splitterless DSL" because, unlike other DSL technologies, it does not require that a technician come to install a splitter, a device that separates voice from data signals, at the home or business (sometimes referred to as "the truck roll").

The G.Lite standard was developed by the Universal ADSL Working Group, whose members include major phone companies in the U.S. and globally, including Ameritech, Bell Atlantic, BellSouth, GTE, MCI, USWest, Sprint, SBC Communications, Deutsche Telekom, France Telecom, British Telecommunications, Singapore Telecom, and Nippon Telegraph and Telephone. Microsoft, Intel, and Compaq are also represented in the Working Group.

The telephone companies and ADSL are competing with the cable TV companies and the **cable modems** to capture the market for fast Internet access. While phone companies conceded the early lead to the cable TV companies, most industry experts believe that G.lite and ADSL will eventually become the dominant technology for most homes and businesses.

The G.Lite standard is officially known as G.992.2.

G

See "gauss"

gain

See "amplification factor"

gallium arsenide field-effect transistor

Also see **metal-oxide semiconductor field-effect transistor**.

A gallium arsenide field-effect transistor (GaAsFET) is a specialized type of field-effect transistor (**FET**) that is used in **amplifier** circuits at very-high, ultra-high, and **microwave** radio frequencies. This spans the **electromagnetic radiation spectrum** from approximately 30 **MHz** up to the infrared band. The GaAsFET is known for its sensitivity, and especially for the fact that it generates very little internal noise. This is because **gallium arsenide** has exceptional carrier mobility. The **electrons** and **holes** move through the **semiconductor** material easily and fast. The GaAsFET is a *depletion-mode* device. This means that it conducts when no **voltage** is applied to the control electrode (gate), and when a voltage appears at the gate, the channel conductivity decreases.

In weak-signal **wireless** communications and broadcast reception, GaAsFET devices perform better than most other types of FET. Some types of GaAsFET are used as radio-frequency (**RF**) power amplifiers. GaAsFETs are employed in space communications, in radio astronomy, and in experiments conducted by amateur radio operators.

gallium arsenide

Gallium arsenide (chemical formula GaAs) is a **semiconductor** compound used in some **diode**, **field-effect transistors** (FETs), and **integrated circuits** (ICs). The charge carriers, which are mostly **electrons**, move at high speed among the **atoms**. This makes GaAs components useful at ultra-high radio frequencies, and in fast electronic switching applications. GaAs devices generate less **noise** than most other types of semiconductor components. This is important in weak-signal amplification.

Gallium arsenide is used in the manufacture of **light-emitting diodes** (LEDs), which are found in optical communications and control systems. Gallium arsenide can replace silicon in the manufacture of linear ICs and **digital** ICs. Linear (also called **analog**) devices include **oscillators** and **amplifiers**. Digital devices are used for electronic switching, and also in computer systems.

gallium nitride

See also **gallium arsenide**.

Gallium nitride (GaN) is a **semiconductor** compound expected to make possible miniaturized, high-power **wireless** transmitters. These transmitters will be combined with sensitive receivers into telephone sets capable of

directly accessing communications **satellite**. The compound can also be used in light-emitting diodes (**LEDs**) and other semiconductor devices.

The advantages of GaN devices include high output power with small physical volume, and high efficiency in power amplifiers at ultra-high and **microwave** radio frequencies.

The main problem with GaN technology is cost. A special process is required to grow a GaN crystal or wafer on which **transistors** and integrated circuits (**ICs**) can be fabricated. Once the process is implemented on a large scale, the cost should come down.

GaN

See "gallium nitride"

Gantt chart

A Gantt chart is a horizontal bar chart developed as a production control tool in 1917 by Henry L. Gantt, an American engineer and social scientist. Frequently used in project management, a Gantt chart provides a graphical illustration of a schedule that helps to plan, coordinate, and track specific tasks in a project. Gantt charts may be simple versions created on graph paper or more complex automated versions created using project management applications such as Microsoft Project or Excel.

A Gantt chart is constructed with a horizontal axis representing the total time span of the project, broken down into increments (for example, days, weeks, or months) and a vertical axis representing the tasks that make up the project (for example, if the project is outfitting your computer with new software, the major tasks involved might be: conduct research, choose software, install software). Horizontal bars of varying lengths represent the sequences, timing, and time span for each task. Using the same example, you would put "conduct research" at the top of the vertical axis and draw a bar on the graph that represents the amount of time you expect to spend on the research, and then enter the other

tasks below the first one and representative bars at the points in time when you expect to undertake them. The bar spans may overlap, as, for example, you may conduct research and choose software during the same time span. As the project progresses, secondary bars, arrowheads, or darkened bars may be added to indicate completed tasks, or the portions of tasks that have been completed. A vertical line is used to represent the report date.

Gantt charts give a clear illustration of project status, but one problem with them is that they don't indicate task dependencies—you cannot tell how one task falling behind schedule affects other tasks. The **PERT chart**, another popular project management charting method, is designed to do this. Automated Gantt charts store more information about tasks, such as the individuals assigned to specific tasks, and notes about the procedures. They also offer the benefit of being easy to change, which is helpful. Charts may be adjusted frequently to reflect the actual status of project tasks as, almost inevitably, they diverge from the original plan.

garbage collecting

Garbage collecting is the recovery of pooled computer **storage** that is being used by a program when that program no longer needs the storage. This frees the storage for use by other programs (or processes within a program). It also ensures that a program using increasing amounts of pooled storage does not reach its quota (in which case it may no longer be able to function).

Some programming languages such as **Java** provide built-in garbage collecting so that the programmer does not have to write code for it.

garbage

In computers, garbage has two related meanings:

- 1) From a user's perceptual point-of-view, garbage is often used to mean anything on your display screen that looks unreadable or unviewable. This can include looking at a graphics file, such as a **Web Graphics Interchange Format** file, with a text reader. Although this is simply an instance of using the wrong program to view a perfectly good file, the viewer is likely to think that what's presented is "garbage."
- 2) From a programming point-of-view, garbage is data that has been placed in **random access memory** space obtained from the operating system that is no longer needed. Freeing the space for reuse is called "garbage collecting." In the past, programmers have had to write programs that explicitly requested storage and then returned it to the system when it was no longer needed. (Programs that neglect to return unused storage can be shut down by the operating system.) The term "garbage collecting" apparently was first used in the **LISP** programming language. **Java** is a newer

programming language that, like LISP, handles garbage-collecting for the program, freeing the programmer from being concerned about it.

gateway

A gateway is a **network** point that acts as an entrance to another network. On the Internet, a **node** or stopping point can be either a gateway node or a **host** (end-point) node. Both the computers of Internet users and the computers that serve pages to users are host nodes. The computers that control traffic within your company's network or at your local Internet service provider (ISP) are gateway nodes.

In the network for an **enterprise**, a computer **server** acting as a gateway node is often also acting as a **proxy server** and a **firewall** server. A gateway is often associated with both a **router**, which knows where to direct a given **packet** of data that arrives at the gateway, and a **switch**, which furnishes the actual path in and out of the gateway for a given packet.

gauss

The gauss (symbolized G) is the centimeter-gram-second (cgs) unit of magnetic flux density. A flux density of 1 G represents one **maxwell** per centimeter squared (1 Mx – cm²). The gauss was named for the German scientist Karl Friedrich Gauss.

The gauss is used when expressing the flux density produced by magnets of the sort commonly encountered in consumer products. The flux density of the earth's magnetic field at the surface is about 1 G. In industrial electromagnetics, the **tesla** (T), a much larger unit, is used to express magnetic flux density. The gauss is one ten-thousandth of a tesla (1 G = 10⁻⁴ T).

Also see **magnetic field**, **tesla**, and **International System of Units**.

GB

See "gigabyte"

GBIC

See "gigabit interface converter"

Gbps

Gbps stands for *billions of bits per second* and is a measure of **bandwidth** on a digital data transmission medium such as **optical fiber**. With slower media and protocols, bandwidth may be in the Mbps (millions of bits or megabits per second) or the Kbps (thousands of bits or kilobits per second) range.

GDMO

GDMO (Guidelines for Definition of Managed Objects) is a standard for defining **objects** in a network in a consistent way. With a consistent "language" for describing such

objects as workstations, LAN servers, and switches, programs can be written to control or sense the status of network elements throughout a network. Basically, GDMO prescribes how a network product manufacturer must describe the product formally so that others can write programs that recognize and deal with the product. Using GDMO, you describe the **class** or classes of the object, how the object behaves, its attributes, and classes that it may inherit.

GDMO is part of the Open Systems Interconnection (OSI) Common Management Information Protocol (CMIP) and also the guideline for defining network objects under the Telecommunications Management Network (TMN), a comprehensive and strategic series of international standards for network management. The object definitions created using GDMO and related tools form a Management Information Base (MIB). GDMO uses Abstract Syntax Notation One (ASN.1) as the rules for **syntax** and attribute encoding when defining the objects.

GDMO is specified in ISO/IEC standard 10165/x.722.

geek speak

Chat abbreviations could be considered a special branch of geek speak.

Geek speak is how the uninitiated refer to the jargon and special vocabulary used by those immersed in computers and other fields of information technology. Geek speak is usually something that someone else uses. (That person may be viewed as a **geek** or just someone who knows more than you.) As a person learns about computers, the terms they use become familiar and only the ones they haven't mastered yet continue to be geek speak. The term was used in press coverage of the 1998 (and ongoing) Microsoft antitrust case in which a great deal of industry jargon was heard from witnesses and in e-mail introduced as evidence.

Geek speak often sounds like normal English that doesn't quite make sense because familiar words have been given a new meaning. A **port** is no longer where a ship docks and a **spool** is no longer what thread comes on. And for that matter, a **thread** is no longer a thin strand of cotton. And executing a program is not at all the same thing as killing it.

geek

In computers and the Internet, a **geek** is a person who is inordinately dedicated to and involved with technology to the point of sometimes not appearing to be normal. Being a **geek** also implies a capability with the technology. Although historically, computer and Internet programming and hacking has been a male thing, there are now many "girl geeks." The term "hacker" generally connotes competence more strongly than "geek" does. The term "geek" emphasizes dedication and weirdness, although recent use of the term suggests greater social acceptance and tolerance for geeks. (Historically, a **geek** was a circus person whose

#

role in the side-show was to bite off chicken's heads or perform other bizarre feats. Eric Raymond describes "computer geek" as "one who eats (computer) bugs for a living.")

A

The term seems to be used by many in the general populace for anyone who spends a lot of or too much time at a computer.

B

C

geekosphere

Assuming you're a computer, Internet, or programming **geek** at least some of the time, the **geekosphere** is the physical ambiance around you and your workstation monitor, including the pasted-up notes, inspirational quotes, family photos, software cheat templates, coffee cup(s), old cans of **Jolt**, mouse pad, pencils, diskettes, more notes, and so forth. The term was mentioned in a *Wired Magazine* article.

J

K

general protection fault

"General protection fault" (or *general protection error*) is a phrase that users of personal computers see when an application program they are running (for example, Microsoft Word or the Netscape Web browser) tries to access storage that is not designated for their use. An operating system (such as Windows 95) manages the use of random access memory (**RAM**) for its own needs and for those of the application programs that it manages. The application programs are actually managed as **task**. When a task attempts to write to a place in RAM that is outside its assigned storage area, the operating system requires that the task or application be closed. Users usually get a message that tells you this is happening, but there isn't much you can do about it other than to restart the program and hope it will run successfully the next time.

L

M

N

O

P

Q

R

S

T

U

V,W

X,Y,Z

If an application program were to be able to write outside of its assigned storage area, it could overwrite other applications' or the operating system's instructions and data. (If that should happen, the operating system would "crash" or close down in some way and you would have to reboot the operating system.) Closing down the errant application protects other applications and the operating system.

A general protection fault is more likely to occur when you are trying out **beta test**-version software. However, even well-seasoned applications can cause a general protection fault because a user hits some combination of keys in quick succession that the programmer could not easily anticipate. A general protection fault can also occur because a system

setting is wrong. If you repeatedly encounter the same general protection fault message, record the details (you are usually given a string of digits that identify exactly where in storage the error is occurring) and call the company that makes the software that seems to be causing the message.

Generalized Markup Language

See "GML"

generic top-level domain name

See "gTLD"

genetic programming

Genetic programming is a model of programming which uses the ideas (and some of the terminology) of biological evolution to handle a complex problem. Of a number of possible programs (usually small program functions within a larger application), the most effective programs survive and compete or cross-breed with other programs to continually approach closer to the needed solution. Genetic programming is an approach that seems most appropriate with problems in which there are a large number of fluctuating variables such as those related to **artificial intelligence**. The genetic programming model is mostly used with the **LISP** and Scheme programming languages. However, it can also be used with **C** and other programming languages.

Genetic programming can be viewed as an extension of the *genetic algorithm*, a model for testing and selecting the best choice among a set of results, each represented by a **string**. Genetic programming goes a step farther and makes the program or "function" the unit that is tested. Two approaches are used to select the successful program—cross-breeding and the tournament or competition approach. A difficult part of using genetic programming is determining *the fitness function*, the degree to which a program is helping to arrive at the desired goal. A simple example of a task suited for genetic programming would be devising a program to fire a gun. The distance by which the bullet misses its target would determine the fitness function.

Genetic programming is a challenging new approach that requires a considerable learning investment for the programmer.

geographic information system

See "GIS"

George Boole

George Boole (1815-1864) was a British mathematician and is known as the founder of mathematical logic. Boole, who came from a poor family and was essentially a self-taught mathematician, made his presence known in the world of mathematics in 1847 after the publication of his book, "The

Mathematical Analysis of Logic." In his book, Boole successfully demonstrated that logic, as Aristotle taught it, could be represented by algebraic equations. In 1854, Boole firmly established his reputation by publishing "An Investigation of the Laws of Thought, on Which Are Founded the Mathematical Theories of Logic and Probabilities," a continuation of his earlier work.

In 1855 Boole, the first professor of mathematics at The College of Cork, Ireland, married Mary Everest, who is now known as a mathematician and teacher in her own right. Mary, who was 18 years younger than Boole, served as sounding-board and editor for her husband throughout their nine years of marriage. Unfortunately, Mary's poor choice of medical treatment may have hastened Boole's death. After getting caught in the rain and catching a cold, Boole was put to bed by his wife, who dumped buckets of water on him based on the theory that whatever had caused the illness would also provide the cure. (It seemed logical to her.) George and Mary had five daughters; the third daughter, Alicia Boole Stott, became well-known for her work in the visualization of geometric figures in hyperspace.

Boole's work in symbolic logic, collectively known as "Boolean algebra," is widely regarded to be based on the work of earlier mathematician G.W. Leibniz. Although Boole's work was well-received during his lifetime, it was considered to be "pure" mathematics until 1938, when Claude Shannon published his thesis at MIT. Shannon demonstrated that Boole's symbolic logic, as it applies to the representation of TRUE and FALSE, could be used to represent the functions of switches in electronic circuits. This became the foundation for digital electronic design, with practical applications in telephone switching and computer engineering.

Today, when using a search engine on the Internet, we use Boole's mathematical concepts to help us locate information by defining a relationship between the terms we enter. For instance, searching for George AND Boole would find every article in which both the word George and the word Boole appear. Searching for George OR Boole would find every article in which either the word George or the word Boole appears. We call this a **Boolean** search.

gesture recognition

Gesture recognition is human interaction with a computer in which human gestures, usually hand motions, are recognized by the computer. Recognizing gestures as input might make computers more accessible for the physically-impaired and make interaction more natural for young children. It could also provide a more expressive and nuanced communication with a computer. Several companies have developed prototype products. Gesture recognition is already being used for interaction with a 3-D immersion environment.

A prototype motion processor developed by Toshiba allows a computer to recognize hand motions and to display them in real-time on the computer's display. Proposed applications include word processing using input with hand sign language, games, and other entertainment and educational approaches in which hand motion could result in multimedia effects.

Toshiba's motion processor works by emitting an **infrared transmission** light near the hand area and "reading" the light reflected back from the hand. Reflections from areas beyond the hand don't occur because the light is quickly dissipated over distance. The reflected light allows the computer to continuously build a 3-D motion image of the hand, which can be displayed or not.

Other forms of gesture recognition than hand gestures are being studied. Finger pointing is one area of study as a way to select or move objects around. Face tracking, eye motion, and lip reading are also being considered as ways to provide interaction. There have also been multimedia experiments in which the entire human body and its range of motions was used to produce computer effects.

ghost

The word "ghost" derives from Old English *gast* and means a disembodied spirit or soul. In information technology, the term has several special meanings:

- 1) Ghost, a product from Symantec, can clone (copy) the entire contents of a **hard disk** to another computer's hard disk, automatically formatting and partitioning the target disk. This product is especially useful where one system is to be replicated on a number of computers.
- 2) On the Web's live chat medium, the Internet Relay Chat (**IRC**), a ghost is a vacated user session that the server believes is still active.
- 3) Ghostscript is a program for **UNIX** systems that interprets a **Postscript** file (which is a file formatted for a Postscript printer) so that, using a related program, Ghostview, you can view it on a display screen.

ghost imaging

Also see **ghost**.

Ghost imaging is the copying of the contents of a computer's **hard disk** into a single compressed **file** or set of files (referred to as an *image*) so that the contents of the hard disk, including configuration information and applications, can be copied to the hard disk of other computers.

An example of ghost imaging software is Norton Ghost, a product from Symantec. Using this product, you can clone (copy) the entire contents of a hard disk to a portable medium such as a writeable CD or to a server. The portable image can then be used to set up each hard disk in other computers, automatically formatting and partitioning each target disk. Ghost imaging is useful where one system is to

be replicated on a number of computers in a classroom or for a team of notebook computer users who all need the same system and applications.

ghost site

Also see **ghost**.

A ghost site is a **Web site** that is no longer maintained but that remains available for viewing. Since many sites don't identify their date of last update, it's not always easy to tell whether a site is a ghost site or just resting. A ghost site is not to be confused with a retired or invisible site (one which doesn't exist anymore and results in a "Not found" message). It's possible to have a ghost site that continues to be useful or appealing because its content doesn't date easily.

A ghost site that for some reason seems to have moved to another location is a **zombie**.

GHz

See "gigahertz"

giant

In networks, a giant is a **packet**, **frame**, cell, or other transmission unit that is too large. Network protocols specify maximum and minimum sizes (and sometimes a single uniform size) for any transmission unit. For example, **ATM** packages all data into 53-byte cells. Any cell larger than that is discarded and recorded as a giant by network monitoring tools. The Remote Network Monitoring (**RMON**) standard information base for network administration calls them "oversize packets."

Also see **runt**.

giant magnetoresistive effect

GMR is the newest generation of **hard disk drive storage**. It provides almost three times the data density of its immediate predecessor, **magnetoresistive head technology**.

Disk storage technology strives to improve areal density—in other words, how much data can be packed into a given space. And where MR technology can store up to 3.3 **gigabytes** per square inch, GMR squeezes in 10 gigabytes per square inch—over 40 gigabytes per drive.

As more data is squeezed into the same amount of space, the devices needed to accurately read the data also must keep pace. GMR is designed to pack as much data onto a disk that can be retrieved accurately—with as few moving parts as possible.

The technology is based on a discovery made by two scientists in the late 1980s. The two—Peter Gruenberg of Julich, Germany and Albert Fert of Paris—figured out that

materials made up of very thin, alternating layers of various metallic and nonmetallic elements experienced significant variations in **resistance**.

Disk drives that are based on GMR use these properties to help control a sensor that responds to very small rotating on the disk. The magnetic rotation yields a very large change in sensor resistance, which in turn provides a signal that can be picked up by the electric circuits in the drive.

GID

1) In a **UNIX** system, a GID (group ID) is a name that associates a system user with other users sharing something in common (perhaps a work project or a department name). It's often used for accounting purposes. A user can be a member of more than one group and thus have more than one GID. Any user using a UNIX system at a given time has both a user ID (UID) and a group ID (GID).

2) In Windows 95, a file with a ".gid" suffix is a global index file. Windows 95 sometimes creates these files to hold information about a help file (the global index file has the same name as the help file but with the .gid suffix) and stores them as hidden files in the same directory as the help files.

GIF

The GIF (the original and preferred pronunciation is DJIF; it stands for Graphics Interchange Format) is one of the two most common file **formats** for graphic images on the World Wide Web. The other is the **JPEG**.

On the Web and elsewhere on the Internet (for example, bulletin board services), the GIF has become a de facto standard form of image. The **LZW compression algorithm** used in the GIF format is owned by Unisys, and companies that make products that exploit the algorithm (including the GIF format) need to license its use from Unisys. In practice, Unisys has not required users of GIF images to obtain a license, although their licensing statement indicates that it is a requirement. Unisys says that getting a license from them does not necessarily involve a fee.

The GIF uses the 2D **raster** data type and is encoded in **binary**. There are two versions of the format, 87a and **GIF89a**. Version 89a (July, 1989) allows for the possibility of an **animated GIF**, which is a short sequence of images within a single GIF file. A **GIF89a** can also be specified for **interlaced GIF** presentation.

A patent-free replacement for the GIF, the Portable Network Graphics (**PNG**) format, has been developed by an Internet committee and major browsers support it or soon will. Meanwhile, many GIF downloaders and Web site builders on the Web continue to be ignorant of or indifferent to the requirement to get a license from Unisys for the use of their algorithm.

GIF89a

A GIF89a graphics file is an image formatted according to Graphics Interchange Format (GIF) Version 89a (July, 1989). There was an earlier Version, 87a, from May of 1987, but most images you will see on the Web have probably been created in the newer format. One of the chief advantages of the newer format is the ability to create an animated image that can be played after transmitting to a viewer.page that moves—for example, a twirling icon or a banner with a hand that waves or letters that magically get larger. In particular, an **animated GIF** is a file in the Graphics Interchange Format specified as GIF89a that contains within the single file a set of images that are presented in a specified order.

gigabit

In data communications, a gigabit is one billion **bits**, or 1,000,000,000 (that is, 10^9) bits. It's commonly used for measuring the amount of data that is transferred in a second between two telecommunication points. For example, **Gigabit Ethernet** is a high-speed form of **Ethernet** (a local area network technology) that can provide data transfer rates of about 1 gigabit per second. Gigabits per second is usually shortened to Gbps.

Some sources define a gigabit to mean 1,073,741,824 (that is, 2^{30}) bits. Although the bit is a unit of the binary number system, bits in data communications are discrete signal pulses and have historically been counted using the decimal number system. For example, 28.8 kilobits per second (**Kbps**) is 28,800 bits per second. Because of computer architecture and memory address boundaries, bytes are always some multiple or exponent of two. See **kilobyte**, etc.

Gigabit Ethernet

Gigabit Ethernet, a transmission technology based on the **Ethernet** frame format and protocol used in local area networks (LANs), provides a data rate of 1 billion bits per second (one **gigabit**). Gigabit Ethernet is defined in the **IEEE 802.3** standard and is currently being used as the **backbone** in many enterprise networks.

Gigabit Ethernet is carried primarily on **optical fiber** (with very short distances possible on copper media). Existing Ethernet LANs with 10 and 100 Mbps cards can feed into a Gigabit Ethernet backbone. An alternative technology that competes with Gigabit Ethernet is **ATM**. A newer standard, **10-Gigabit Ethernet**, is also becoming available.

gigabit interface converter

A gigabit interface converter (GBIC) is a **transceiver** that converts electric currents (digital highs and lows) to optical signals, and optical signals to digital electric currents. The GBIC is typically employed in **fiber optic** and **Ethernet** systems as an interface for high-speed networking. The data transfer rate is one gigabit per second (1 **Gbps**) or more.

GBIC modules allow technicians to easily configure and upgrade electro-optical communications networks. The typical GBIC transceiver is a plug-in module that is **hot-swappable** (it can be removed and replaced without turning off the system). The devices are economical, because they eliminate the necessity for replacing entire boards at the system level. Upgrading can be done with any number of units at a time, from an individual module to all the modules in a system.

gigabyte

A gigabyte (pronounced GIG-a-bite with hard G's) is a measure of computer data storage capacity and is "roughly" a billion bytes. A gigabyte is two to the 30th power, or 1,073,741,824 in decimal notation.

Also see **gigabit**, **megabyte**, **terabyte**, and **exabyte**.

gigaflop

As a measure of computer speed, a gigaflop is a billion floating-point operations per second (**FLOPS**).

gigahertz

The gigahertz, abbreviated GHz, is a unit of alternating current (AC) or electromagnetic (EM) wave frequency equal to one thousand million **hertz** (1,000,000,000 Hz). The gigahertz is used as an indicator of the frequency of ultra-high-frequency (UHF) and **microwave** EM signals and also, in some computers, to express microprocessor **clock speed**.

An EM signal having a **frequency** of 1 GHz has a **wavelength** of 300 millimeters, or a little less than a foot. An EM signal of 100 GHz has a wavelength of 3 millimeters, which is roughly $\frac{1}{8}$ of an inch. Some radio transmissions are made at frequencies up to hundreds of gigahertz. Personal computer clock speeds are increasing month by month as the technology advances, and reached the 1 GHz point in March of 2000, with a processor from **AMD**, closely followed by a 1 GHz **Pentium 3** from Intel.

Other commonly-used units of frequency are the **kHz**, equal to 1,000 Hz or 0.000001 GHz, and the **MHz**, equal to 1,000,000 Hz or 0.001 GHz.

GIMP

GIMP, sometimes referred to as "The Gimp," is a freely available **open source** application for created and manipulating graphic images that runs on **Linux** and other **UNIX**-based operating systems. GIMP is distributed under licensing terms defined by the **GNU** project. You are likely to find GIMP as one of the optional applications that come in any large Linux package such as those distributed by **Debian** and **Red Hat**. You can also download it directly. GIMP offers photo retouching, image composition, and

image authoring and is favorably compared by users to Adobe's Photoshop and Illustrator applications. GIMP was created by Peter Mattis and Spencer Kimball.

GIS

A GIS (geographic information system) enables you to envision the geographic aspects of a body of data. Basically, it lets you query or analyze a and receive the results in the form of some kind of map. Since many kinds of data have important geographic aspects, a GIS can have many uses: weather forecasting, sales analysis, population forecasting, and land use planning, to name a few.

In a GIS, geographic information is described explicitly in terms of geographic coordinates (latitude and longitude or some national grid coordinates) or implicitly in terms of a street address, postal code, or forest stand identifier. A geographic information system contains the ability to translate implicit geographic data (such as a street address) into an explicit map location. GIS developers sometimes obtain the map data from public sources or companies that specialize in collecting and organizing geographic information. The process of converting implicit geographic data into explicit or map-form images is called *geocoding*.

Geographic data can be stored in a **vector graphics** or a **raster graphics** format. Using a vector format, two-dimensional data is stored in terms of **x and y coordinates**. A road or a river can be described as a series of x,y coordinate points. Nonlinear features such as town boundaries can be stored as a closed loop of coordinates. The vector model is good for describing well-delineated features. A raster data format expresses data as a continuously-changing set of grid cells. The raster model is better for portraying subtle changes such as soil type patterns over an area. Most geographic information systems make use of both kinds of data.

GISs do these kinds of things:

- They accept geographic input in the form of scanned-in and digitized map images. Often this data is supplied by a source that may own maps and has already digitized them.
- They rescale or otherwise manipulate geographic data for different purposes.
- They include a database manager, usually a relational database management system (**RDBMS**).
- They include query and analysis programs so that you can retrieve answers to simple questions such as the distance between two points on a map or more complicated questions that require analysis, such as determining the traffic pattern at a given intersection.
- They provide answers visually, usually as maps or graphs.

glass house

Glass house is a term for centralized computing in an **enterprise** and the mindset of those who plan and administer it. The term originated from the glass windows that, beginning in the 1950s, corporations began to build into their large central computer rooms to let visitors peer in on their impressive rows of **mainframe** computers, direct access storage devices and tape racks, and other hardware. These large rooms were built with an elevated floor that could accommodate, underneath the floorboards, telecommunications and local channel cabling as well as water pipes for cooling the larger water-cooled mainframes. As hardware technology and physical footprints have changed, the physical glass house has changed or even disappeared into smaller spaces and closets. However, much computing in an enterprise remains (and is expected to remain) centrally administered and, to the extent that it does, the glass house point-of-view remains in fashion.

glitch

In several usages in information technology, a *glitch* (pronounced GLIHTCH) is a sudden break in function or continuity, sometimes of a transient nature, with a varying degree of seriousness. According to Eric Raymond, author of *The New Hacker's Dictionary*, glitch is from the German "glitschen," meaning "to slip," via Yiddish "glitschen," meaning "to slide or skid." In different contexts, the term has different meanings.

- 1) In electrical service, a glitch, sometimes called a *power glitch*, is a momentary power failure.
- 2) In network service, a glitch can be any temporary loss of service in the network.
- 3) In a computer program, a glitch can be a **bug** that isn't encountered very often, resulting in a problem that sometimes goes away because next time the combination of events is different. Glitches like this are often encountered with Web **browsers**. (Browser glitches are often fixed by closing the browser program and then reopening it, or by restarting the operating system.) A glitch can also be an intentionally planned trap or other program device that results in exposing a user's password or in some other security breach.
- 4) In computer **audio**, a glitch is a quick temporary noise in a file that sounds like a "snap."

Glite

See "G.lite"

Global Positioning System

The GPS (Global Positioning System) is a "constellation" of 24 well-spaced satellites that orbit the Earth and make it possible for people with ground receivers to pinpoint their

geographic location. The location accuracy is anywhere from 100 to 10 meters for most equipment. Accuracy can be pinpointed to within one (1) meter with special military-approved equipment. GPS equipment is widely used in science and has now become sufficiently low-cost so that almost anyone can own a GPS receiver.

The GPS is owned and operated by the U.S. Department of Defense but is available for general use around the world. Briefly, here's how it works:

- 21 GPS satellites and three spare satellites are in orbit at 10,600 miles above the Earth. The satellites are spaced so that from any point on Earth, four satellites will be above the horizon.
- Each satellite contains a computer, an atomic clock, and a radio. With an understanding of its own orbit and the clock, it continually broadcasts its changing position and time. (Once a day, each satellite checks its own sense of time and position with a ground station and makes any minor correction.)
- On the ground, any GPS receiver contains a computer that "triangulates" its own position by getting bearings from three of the four satellites. The result is provided in the form of a geographic position—longitude and latitude—to, for most receivers, within 100 meters.
- If the receiver is also equipped with a display screen that shows a map, the position can be shown on the map.
- If a fourth satellite can be received, the receiver/computer can figure out the altitude as well as the geographic position.
- If you are moving, your receiver may also be able to calculate your speed and direction of travel and give you estimated times of arrival to specified destinations.

The GPS is being used in science to provide data that has never been available before in the quantity and degree of accuracy that the GPS makes possible. Scientists are using the GPS to measure the movement of the arctic ice sheets, the Earth's tectonic plates, and volcanic activity.

GPS receivers are becoming consumer products. In addition to their outdoor use (hiking, cross-country skiing, ballooning, flying, and sailing), receivers can be used in cars to relate the driver's location with traffic and weather information.

glyph

In information technology, a glyph (pronounced GLIHF) is a graphic symbol that provides the appearance or form for a **character**. A glyph can be an alphabetic or numeric **font** or some other symbol that pictures an encoded character. The following quote is from a document written as background for the **Unicode** character set standard.

An ideal characterization of characters and glyphs and their relationship may be stated as follows:

1. A character conveys distinctions in meaning or sounds. A character has no intrinsic appearance.
2. A glyph conveys distinctions in form. A glyph has no intrinsic meaning.
3. One or more characters may be depicted by one or more glyph representations (instances of an abstract glyph) in a possibly context dependent fashion.

Glyph is from a Greek word for "carving."

GML

GML (Generalized Markup Language) is an IBM document-formatting language that describes a document in terms of its organization structure and content parts and their relationship. GML **markup** or **tags** describe such parts as chapters, important sections and less important sections (by specifying heading levels), paragraphs, lists, tables, and so forth. GML frees document creators from specific document formatting concerns such as **font** specification, line spacing, and page layout required by IBM's printer formatting language, SCRIPT.

GML Starter Set is the name of IBM's set of GML tags. GML Starter Set input is processed by the Document Composition Facility (DCF) which formats printer-ready output. A later and more capable set of GML tags is provided by IBM's BookMaster product.

GML preceded and was an inspiration for the industry-developed Standard Generalized Markup Language (SGML), today's strategic set of rules for creating any structured document description language. This Web page is marked up with Hypertext Markup Language (HTML) tags and is an example of a document that makes use of GML concepts. The Extensible Markup Language (XML) also has roots in GML.

GMT

See "Coordinated Universal Time"

GNOME

GNOME (GNU Network Object Model Environment, pronounced gah-NOHM) is a graphical user interface (GUI) and set of computer **desktop applications** for users of the **Linux** computer operating system. It's intended to make a Linux operating system easy to use for non-programmers and generally corresponds to the Windows desktop interface and its most common set of applications. In fact, GNOME allows the user to select one of several desktop appearances. With GNOME, the user interface can, for example, be made to look like **Windows 98** or like **Mac OS**. In addition, GNOME includes a set of the same type of applications found in the Windows Office 97 product: a **word processor**, a spreadsheet program, a **database manager**, a presentation developer, a **Web browser**, and an **e-mail** program.

GNOME is derived from a long-running volunteer effort under the auspices of the **Free Software Foundation**, the organization founded by Richard Stallman. Stallman and fellow members of the Free Software Foundation believe that software **source code** should always be public and **open** to change so that it can continually be improved by others. GNOME is in part an effort to make Linux a viable alternative to Windows so that the desktop operating system market is not controlled by a single vendor. **GNU** is the Free Software Foundations's own operating system and set of applications. **Linux**, the operating system, was developed by Linus Torvalds who, assisted by contributors, added a **kernel** to additional operating system components from GNU.

GNOME comes with an object request broker (**ORB**) supporting the Common Object Request Broker Architecture (**CORBA**) so that GNOME programs and programs from other operating system platforms in a network will be able to interoperate. GNOME also includes a **widget** library that programmers can use to develop applications that use the GNOME user interface. In addition to a desktop version, GNOME also comes as a user interface and set of applications for the handheld PalmPilot.

GNU Network Object Model Environment

See "GNOME"

GNU

GNU is a **UNIX-like operating system** that comes with source code that can be copied, modified, and redistributed. The GNU project was started in 1983 by Richard Stallman and others, who formed the **Free Software Foundation**. Stallman believes that users should be free to do whatever they want with software they acquire, including making copies for friends and modifying the source code and repackaging it with a distribution charge. The FSF uses a stipulation that it calls **copyleft**. Copyleft stipulates that anyone redistributing free software must also pass along the

freedom to further copy and change the program, thereby ensuring that no one can claim ownership of future versions and place restrictions on users.

The "free" means "freedom," but not necessarily "no charge." The Free Software Foundation does charge an initial distribution price for GNU. Redistributors can also charge for copies either for cost recovery or for profit. The essential idea of "free software" is to give users freedom to how they modify or repackage the software along with a restriction that they in turn do not restrict user freedom when they pass copies or modified versions along.

One of the results of the free software philosophy, Stallman believes, would be free programs put together from other free programs. GNU is an example of this idea. It became a complete operating system in August 1996, when a **kernel**, consisting of GNU Hurd and Mach, was added. The FSF plans to continue developing their free software in the form of application programs. A free spreadsheet program is now available.

The **Linux** operating system consists of GNU components and the kernel developed by Linus Torvalds.

Gnutella

Gnutella is a system in which individuals can exchange files over the Internet directly without going through a Web site in an arrangement sometimes described as **peer-to-peer** (here meaning "person-to-person"). Like **Napster** and similar Web sites, Gnutella is often used as a way to download music files from or share them with other Internet users and has been an object of great concern for the music publishing industry. Unlike Napster, Gnutella is not a Web site, but an arrangement in which you can see the files of a small number of other Gnutella users at a time, and they in turn can see the files of others, in a kind of daisy-chain effect. Gnutella also allows you to download any file type, whereas Napster is limited to **MP3** music files.

After installing and launching Gnutella, a user's computer (node) becomes both a **client** and a **server** in the network (which is called GnutellaNet) and is able to share files that other Gnutella users have set up to make available. Gnutella, whose name pays homage to both the hazelnut/chocolate spread "Nutella" and the **GNU** project of the Free Software Foundation, was originally developed by Nullsoft (creators of MP3 and WinAMP). It was never publicly released because Nullsoft's parent corporation (AOL) declared the work an "unauthorized publication." However, the **beta** version that was made available for preview was an **open source** program, which resulted in any number of clone variations becoming available that AOL does not own.

Although Gnutella and its variants have incurred the wrath of some musicians and the music industry, the defenders of the peer-to-peer approach view it as a new movement that

frees individuals to exchange information with each other directly without the supervision and restrictions of brokering Web sites or other third-parties.

go bosh

Go bosh is cyberspeak for “Go Big or Stay Home,” meaning that if you don’t commit enough resources to your enterprise, you’ll probably fail in your objectives. The term is sometimes used to refer to new Web sites or enterprises that need to gain enough traffic to be able to compete for advertising with similar sites. Web analysts predict that in any given market niche only a few Web sites will be able to establish themselves well enough to succeed in the long run.

going forward

Going forward is a relatively new and apparently convenient way to indicate a progression in time from the present. The term suggests a continuing and progressive movement rather than, as *in the future* can sometimes mean, some specific future date. Like many such expressions, it means enough to be useful while also being suitably vague. The term is widely used in annual reports and other corporate statements and, like such terms as *venue* and *cautionary tale*, seems to have been readily adopted by news media writers. The term has become increasingly popular in press releases from Internet start-ups and newly public companies.

“Going forward” also has a longer-standing usage as the starting, continuing, or resumption of activity on something that has been planned previously, such as an engineering project or a summit conference.

googol and googolplex

A googol is 10 to the 100th power (which is 1 followed by 100 zeros). The term was invented by Milton Sirota, the 9-year nephew of mathematician Edward Kasner, who had asked his nephew what he thought such a large number should be called. Such a number, Milton apparently replied after a short thought, could only be called something as silly as...a *googol*! A googol is larger than the number of elementary particles in the universe, which amount to only 10 to the 80th power.

Later, another mathematician devised the term *googolplex* for 10 to the power of googol—that is, 1 followed by 10 to the power of 100 zeros. Frank Pilhofer has determined that, given **Moore’s Law** (which is that computer processor power doubles about every 1 to 2 years), it would make no sense to try to print out a googolplex for another 524 years—since all earlier attempts to print a googolplex out would be overtaken by the faster processor.

gov

“gov” is one of the top-level **domain names** that can be used when choosing a domain name. It generally describes the entity owning the domain name as a branch or an agency of the U.S. Federal government. (Other U.S. government levels are encouraged to use the geographic top-level domain name of “us”.) Along with the second-level domain name (for example: “whitehouse” in whitehouse.gov), the top-level domain name is required in Web and e-mail addresses.

For more information, see **gTLD** (generic top-level domain name).

GPRS

General Packet Radio Services (GPRS) is a **packet-based wireless** communication service that promises data rates from 56 up to 114 **Kbps** and continuous connection to the Internet for mobile phone and computer users. The higher data rates will allow users to take part in video conferences and interact with multimedia Web sites and similar applications using mobile **handheld** devices as well as notebook computers. GPRS is based on Global System for Mobile (**GSM**) communication and will complement existing services such **circuit-switched** cellular phone connections and the Short Message Service (**SMS**).

In theory, GPRS packet-based service should cost users less than circuit-switched services since communication channels are being used on a shared-use, as-packets-are-needed basis rather than dedicated only to one user at a time. It should also be easier to make applications available to mobile users because the faster data rate means that **middleware** currently needed to adapt applications to the slower speed of wireless systems will no longer be needed. As GPRS becomes available, mobile users of a virtual private network (**VPN**) will be able to access the private network continuously rather than through a dial-up connection.

GPRS will also complement **Bluetooth**, a standard for replacing wired connections between devices with wireless radio connections. In addition to the Internet Protocol (**IP**), GPRS supports **X.25**, a packet-based protocol that is used mainly in Europe. GPRS is an evolutionary step toward Enhanced Data GSM Environment (**EDGE**) and Universal Mobile Telephone Service (**UMTS**).

GPS

See “Global Positioning System”

Grace Hopper

Grace Murray Hopper, one of the pioneers of computer science, is generally credited with developments that led to **COBOL**, the programming language for business applications on which the world’s largest corporations ran for more than a generation. By the time of her death in 1992, Rear Admiral Grace Hopper had left many contributions to

the field of software engineering and was arguably the world's most famous programmer. After receiving her Ph.D. in mathematics at Yale, Hopper worked as an associate professor at Vassar College before joining the U.S. Naval Reserve in 1943. She went on to work as a researcher and mathematician at the Eckert-Mauchly Computer Corp. and the Sperry Corporation. Having retired from the Navy after World War II, she returned in 1967 to work at the Naval Data Automation Command.

At Eckert-Mauchly, Hopper developed programs for the first large-scale digital computer, the Mark I. She also developed the first **compiler**, the A-O. She published the first paper on compilers in 1952. The successor to the the A-O, named FLOW-MATIC, led to the development of the COBOL programming language. Until then programming was done using **assembler** language. Admiral Hopper's idea was to make a programming language closer to ordinary language so that it could be used by non-technical people, thus opening the practice of programming to the business world and freeing it from the rarefied environments of science and engineering.

Admiral Hopper remained in the Navy until 1986 and then worked as a senior consultant for DEC until shortly before her death. She was highly sought after as an enthusiastic and entertaining public speaker and educator of young programmers. Hopper was an early advocate of the use of shared code libraries and developed compiler verification software and compiler standards. Hopper is also sometimes mistakenly credited with inventing the term **bug**, a flaw in a computer or a program.

gram

The gram (abbreviation, g or gm) is the **cgs** (centimeter/gram/second) unit of **mass**. A force of one **dyne** (1 dyn), applied to a mass of one gram (1 g), will cause that mass to accelerate at one centimeter per second squared (1 cm/s²).

Mass is often specified in larger or smaller units than the gram, by changing the power-of-10 **prefix multiplier**. A mass of one kilogram (1 kg) is 1000 g. A mass of one milligram (1 mg) is 0.001 g. A mass of one microgram (1 µg) is 10⁻⁶ g. A mass of one nanogram (1 ng) is 10⁻⁹ g. In the International System of Units (**SI**), the kilogram is the preferred unit of mass.

Also see **kilogram**, **mass**, **small-unit metric system**, and International System of Units (**SI**).

granularity

Granularity is the relative size, scale, level of detail, or depth of penetration that characterizes an object or activity. It may help to think of it as: Which type of "granule" are we looking at? This term is used in astronomy, photography, physics, linguistics, and fairly often in information technology. It can refer to the level of a hierarchy of objects or actions, to the fineness of detail in a photograph, or to the amount of

information that is supplied in describing a person's age. Its meaning is not always immediately clear to those unfamiliar with the context in which it's being used.

graphical user interface

See "GUI"

graphics accelerator

A graphics accelerator (a **chipset** attached to a *video board*) is a computer microelectronics component to which a computer program can offload the sending and refreshing of images to the display monitor and the computation of special effects common to 2-D and 3-D images. Graphics accelerators speed up the displaying of images on the monitor making it possible to achieve effects not otherwise possible—for example, the presentation of very large images or of interactive games in which images need to change quickly in response to user input. Many new personal computers are now sold with a graphics accelerator built in. The power of a graphics accelerator can be extended further if the personal computer is equipped with the Accelerated Graphics Port (**AGP**), a bus (data path) interface between the computer components involved in image display.

Each graphics accelerator provides an application program interface (**API**). Some support more than one API. Among the most popular API's are the industry standard **OpenGL** and Microsoft's **DirectX** and Direct3D.

Graphics Interchange Format

See "GIF"

grasping plan

A grasping plan is an **algorithm** used by a **robot** arm and gripper to get hold of a specific object. The details of such a program depend on the type of robot arm and gripper, on the size of the robot's work area, and on the type of object(s) to be grasped.

As an example, imagine you own a mobile, autonomous personal robot. You are having spaghetti with lots of sauce for supper, so you feel compelled to instruct the machine to get you six paper napkins. The robot must use a certain program to find the kitchen, another program to locate the cabinet or drawer in which the napkins are stored, and another program to determine which objects in the drawer are the paper napkins. Then the gripper must pick up exactly six napkins without upsetting the other contents of the drawer or cabinet. This is a simple process for a human being, even a child, to carry out, but it is complex when reduced to digital components. There are myriad ways in which the robot might execute this assignment wrong, but only one way to do it right.

A grasping plan can be enhanced by **machine vision**. Tactile sensors, pressure sensors, and texture sensors can also help ensure that the gripper picks up the correct object in the right way. An efficient and reliable grasping plan involves the use of a detailed, three-dimensional map of the robot's entire work environment, stored in the robot controller's memory. The grasping plan can then assign every object or set of objects a range of coordinate values.

Also see **artificial intelligence**, fine-motion plan, gross-motion plan, and **robotics**.

grating light valve

Using grating light valve (GLV) technology, picture elements (**pixels**) are formed on the surface of a silicon chip and become the source for display projection on anything from an auditorium screen down to a handheld computer display. Using GLV, displays of the future may cost much less, require less space, and make high-resolution images possible in handheld personal communication devices. GLV was developed by David Bloom together with his students at Stanford University. Bloom has since founded Silicon Light Machines, which is developing the technology further.

GLV uses micro-electromechanical systems (**MEMS**) technology and optical physics to vary how light is reflected from each of multiple ribbon-like structures that represent a particular "image point" or pixel. The ribbons can move a tiny distance, changing the wavelength of reflected light. Grayscale tones are achieved partly by varying the speed at which given pixels are switched on and off. The resulting image can be projected in a large auditorium with a bright light source or on a small appliance using low-power LEDs as a light source.

gravesite

In the context of the World Wide Web, a gravesite is either:

- 1) A **Web site** that has been abandoned or forgotten by its originators that is nevertheless still accessible on a server. (There is a vast but untold number of these.) A synonym is **ghost site**.
- 2) A Web site that, in the eyes of marketers, has failed to get sufficient traffic to be interesting to advertisers or other revenue providers, possibly by not finding an audience niche or building an audience community, or by failing to find a distribution partner such as America Online, Yahoo, or Netscape.

gray hat

Gray hat describes a **cracker** (or, if you prefer, **hacker**) who exploits a security weakness in a computer system or product in order to bring the weakness to the attention of the owners. Unlike a **black hat**, a gray hat acts without malicious intent. The goal of a gray hat is to improve system and network security. However, by publicizing a

vulnerability, the gray hat may give other crackers the opportunity to exploit it. This differs from the **white hat** who alerts system owners and vendors of a vulnerability without actually exploiting it in public.

gray

The gray (symbolized Gy) is the standard unit of absorbed ionizing-radiation dose, equivalent to one **joule** per kilogram ($1 \text{ J} \cdot \text{kg}^{-1}$). Reduced to base units in the International System of Units (**SI**), 1 Gy is equivalent to one **meter squared per second squared** ($1 \text{ m}^2 \cdot \text{s}^{-2}$).

In general, ionizing-radiation dose is the amount of X-ray, gamma-ray, or high-speed-particle **energy** absorbed per unit **mass**. The gray supersedes the **rad**, an older unit of radiation dose. In some documents the rad is still used; the gray is 100 times larger. If D_g is the radiation dose in grays and D_r is the radiation dose in rads, then the following formulas can be used for conversion:

$$D_r = 100 D_g$$

$$D_g = 0.01 D_r$$

Also see **gray per second**, **sievert**, International System of Units (**SI**).

Gregorian calendar

The Gregorian calendar is the calendar in current use in the Western world, both as the civil and Christian ecclesiastical calendar. Instituted by Pope Gregory XIII in 1582, the calendar has 365 days with an extra day every four years (the leap year) except in years divisible by 100 but not divisible by 400. Thus, the calendar year has an average length of 365.2422 days. The Gregorian calendar replaced the **Julian calendar**, which had become 10 days out of synchrony with the solar cycle. In October, 1582, 10 days were dropped from the calendar. England and the American colonies were late in adopting the calendar. In 1752, they dropped 11 days.

grep

Grep, a **UNIX** command and also a utility available for Windows and other operating systems, is used to search one or more files for a given character string or pattern and, if desired, replace the character string with another one. For example, a UNIX system user can enter on a command line:

```
grep html homepage.htm
```

html specifies the character string to search for on each line. *homepage.htm* specifies the file to search. The result would be to display any line in the *homepage.htm* file that includes the character string *html*. The entire line is displayed.

Grep can be used simply as a way of searching, especially through multiple files. (In the above command, we could have specified additional files besides *homepage.htm*.) It can also be used to search for word or string occurrences that need to be replaced. If you are not sure exactly what the

A
B
C
D
E
F
G
H
I
J
K
L
M
N
O
P
Q
R
S
T
U
V,W
X,Y,Z

effect might be of making the replacement, `grep` identifies the lines and you can decide what further action to take for each occurrence. `grep` can also be used as the first step in an automatic procedure to search and replace a word or phrase. The output from `grep` can be the input (perhaps using the UNIX **pipe** symbol) for a replacement command.

`grep` allows the string argument to be specified as a *regular expression*, which is a way of specifying a string that allows certain *metacharacters* (special keyboard characters such as the period) to stand for other characters or to further define the way the pattern-matching should work. For example:

`grep *.hood essay1` would search the *essay1* file and display every line containing a word with the string *hood*. The period (dot) indicates that any character may precede the string *hood* and the asterisk (*) says that any number of the "any characters" indicated by the dot can precede the string. (The quote marks around the string argument in this example are optional, but quotes are required where the argument is a phrase or contains a blank.)

`grep` originated from a UNIX text editor that provided a command sequence *g/re/p* for *global/regular expression/print*.

grey hat

See "gray hat"

grok

To grok (pronounced GRAHK) something is to understand something so well that it is fully absorbed into oneself. In Robert Heinlein's science-fiction novel of 1961, *Stranger in a Strange Land*, the word is Martian and literally means "to drink" but metaphorically means "to take it all in," to understand fully, or to "be at one with." Today, grok sometimes is used to include acceptance as well as comprehension—to "dig" or appreciate as well as to know.

As one character from Heinlein's novel says:

'Grok' means to understand so thoroughly that the observer becomes a part of the observed—to merge, blend, intermarry, lose identity in group experience. It means almost everything that we mean by religion, philosophy, and science—and it means as little to us (because we are from Earth) as color means to a blind man.

In common usage, "Do you grok?" seems close in meaning to "Do you get it?"

ground-plane antenna

A ground-plane antenna is a variant of the **dipole antenna**, designed for use with an unbalanced **feed line** such as **coaxial cable**. It resembles a **coaxial antenna** whose lower section consists of straight elements called *radials* instead of a hollow conducting cylinder. There are two or more radials, each measuring $\frac{1}{4}$ **wavelength**. The main element can be any length, but it must be adjusted to function at and near a

specific **frequency**. This adjustment is done using a tuning coil. The radials are connected to the outer conductor or shield of the feed line cable; the main element is connected to the center conductor.

The main element of a ground-plane antenna is almost always oriented vertically. This results in transmission of, and optimum response to, vertically polarized **wireless** signals. When the base of the antenna is placed at least $\frac{1}{4}$ wavelength above the ground or other conducting surface, the radials behave as a near-perfect ground system for an **electromagnetic field**, and the antenna is highly efficient. It works equally well in all horizontal directions. Ground-plane antennas are favored at frequencies above approximately 10 **MHz** where the dimensions are manageable. This type of antenna is especially popular among Citizens Band radio operators for fixed-station use in the class-D band at 27 MHz.

groupware

Groupware refers to programs that help people work together collectively while located remotely from each other. Groupware services can include the sharing of calendars, collective writing, e-mail handling, shared database access, electronic meetings with each person able to see and display information to others, and other activities.

Some product examples of groupware include Lotus Notes and Microsoft Exchange, both of which facilitate calendar sharing, e-mail handling, and the replication of files across a distributed system so that all users can view the same information. Electronic "face-to-face" meetings are facilitated by **CU-SeeMe** and Microsoft NetMeeting.

GSM

GSM (Global System for Mobile communication) is a **digital** mobile telephone system that is widely used in Europe and other parts of the world. GSM uses a variation of time division multiple access (**TDMA**) and is the most widely used of the three digital **wireless** telephone technologies (TDMA, GSM, and CDMA). GSM digitizes and compresses data, then sends it down a channel with two other streams of user data, each in its own time slot. It operates at either the 900 **MHz** or 1800 MHz frequency band.

GSM is the de facto wireless telephone standard in Europe. GSM has over 120 million users worldwide and is available in 120 countries, according to the GSM MoU Association. Since many GSM network operators have roaming agreements with foreign operators, users can often continue to use their mobile phones when they travel to other countries.

American Personal Communications (APC), a subsidiary of Sprint, is using GSM as the technology for a **broadband** personal communications service (**PCS**). The service will ultimately have more than 400 base stations for the palm-sized handsets that are being made by Ericsson, Motorola, and Nokia. The handsets include a phone, a text pager, and an answering machine.

GSM together with other technologies is part of an evolution of wireless mobile telecommunication that includes High-Speed Circuit-Switched Data (**HCS**D), General Packet Radio System (**GPRS**), Enhanced Data GSM Environment (**EDGE**), and Universal Mobile Telecommunications Service (**UMTS**).

GTAG

GTAG (Global Tag) is a standardization initiative of the Uniform Code Council (UCC) and the European Article Numbering Association (**EAN**) for asset tracking and logistics based on radio frequency identification (**RFID**). EAN and UCC launched the GTAG project in March of 2000, and—along with input from international companies including Philips Semiconductors, Intermec, and Gemplus—are expected to publish their final guidelines by May 2002. The Initiative intends to increase the range and complexity of typical current RFID applications, such as automatic road toll collection and anti-theft technologies, to sophisticated *smart tag* RFID products as small as a postage stamp that can be used to track inventory and deter theft, among a myriad of potential uses.

The RFID smart tag devices are basically very small database applications that receive information via radio frequency (**RF**) waves. In the future, this capability will automate an increasing number of tasks. For example, a library patron or store customer would no longer have to stop at a cash register or a library check out. RFID devices would store information about both the patron and their selections, which would be transmitted to electronic equipment and updated in all associated system components. The RFID

devices are still much more expensive than the magnetic tags commonly used now (about \$1 per tag, compared to \$.03), but as prices come down and the practical and cost benefits of RFID smart tags become more widely known, they are likely to be seen in an increasing number of applications. There are still some privacy and security issues to be resolved however, since the information stored in tags—which may not be encrypted—can be read by anyone with the requisite equipment, to a distance of several feet.

gTLD

A gTLD (generic top-level domain name) is the **top-level domain** name of an Internet address that identifies it generically as associated with some domain class, such as .com (commercial), .net (originally intended for Internet service providers, but now used for many purposes), .org (for non-profit organizations, industry groups, and others), .gov (U.S. government agencies), .mil (for the military), .edu (for educational institutions); and .int (for international treaties or databases and not much used). For example, in the domain name, www.ibm.com, .com is the chosen gTLD. In addition to the gTLD, there is the ccTLD (country code top-level domain name) that identifies a specific national domicile for an address. (For instance, .fr for France and .mx for Mexico.)

In November 2000, the Internet Corporation for Assigned Names and Number (**ICANN**), a Los Angeles-based non-profit group that oversees the distribution of domain names, approved seven additional gTLDs. The new gTLDs are .biz, restricted to businesses; .info, open to anyone; .name, for personal registrations; .pro, for licensed professionals such as lawyers, doctors and accountants; .aero, for anything related to air transport; .museum, for museums; and .coop, for co-operative businesses such as credit unions. The group selected these new gTLDs from among more than 40 proposed suffixes. It rejected gTLDs such as .kid, .site, .xxx, .home, .dot, and .site. ICANN is currently negotiating registry agreements with the gTLD applicants it chose.

Proponents of adding new gTLDs argue that they are easy to create and free up new space for Internet addresses. Those opposed say more gTLDs only lead to confusion and pose an increased risk of trademark infringement, **cybersquatting**, and cyberpiracy.

ICANN has approved several organizations to register domain names for individuals and businesses. The group has not yet accredited anyone to pre-register names in any of the new gTLDs, and those attempting it do so at their own risk.

GUI

Also see **HCI** (human-computer interaction).

A GUI (usually pronounced GOO-ee) is a graphical (rather than purely textual) user interface to a computer. The term came into existence because the first interactive user

interfaces to computers were not graphical; they were text-and-keyboard oriented and usually consisted of commands you had to remember and computer responses that were infamously brief. The command interface of the **DOS** operating system (which you can still get to from your Windows operating system) is an example of the typical user-computer interface before GUIs arrived. An intermediate step in user interfaces between the command line interface and the GUI was the non-graphical *menu-based interface*, which let you interact by using a **mouse** rather than by having to type in keyboard commands.

Today's major operating systems provide a graphical user interface. Applications typically use the elements of the GUI that come with the operating system and add their own graphical user interface elements and ideas. A GUI sometimes uses one or more metaphors for objects familiar in real life, such as the **desktop**, the view through a window, or the physical layout in a building. Elements of a GUI include such things as: windows, pull-down menus, buttons, scroll bars, iconic images, wizards, the mouse, and no doubt many things that haven't been invented yet. With the increasing use of multimedia as part of the GUI, sound, voice, motion video, and virtual reality interfaces seem likely to become part of the GUI for many applications. A system's graphical user interface along with its input devices is sometimes referred to as its "look-and-feel."

The GUI familiar to most of us today in either the Mac or the Windows operating systems and their applications originated at the Xerox Palo Alto Research Laboratory in the late 1970s. Apple used it in their first Macintosh computers. Later, Microsoft used many of the same ideas in their first version of the Windows operating system for IBM-compatible PCs.

When creating an application, many object-oriented tools exist that facilitate writing a graphical user interface. Each GUI element is defined as a **class widget** from which you can create **object** instances for your application. You can code or modify prepackaged methods that an object will use to respond to user stimuli.

GUID

A GUID (global unique identifier) is a term used by Microsoft for a number that its programming generates to create a unique identity for an entity such as a Word document. GUIDs are widely used in Microsoft products to identify interfaces, replica sets, records, and other objects. Different kinds of objects have different kinds of GUIDs—for instance, a Microsoft Access database uses a 16-byte field to establish a unique identifier for replication.

The nature of certain of Microsoft's GUIDs, the use made of GUIDs, and the potential for abuse arising out of GUIDs, have raised concern among privacy advocates. In March 1999, a request was made to the U.S. Federal Trade Commission to investigate Microsoft's use of GUIDs.

The controversy relates especially to GUIDs attached to Office 97 and Office 2000 documents. The GUID numbers generated for Office documents on Mac and networked PCs have been found to incorporate the unique identification number of the computer's card. The fact that Office documents, such as a Word file or an Excel spreadsheet, contain a GUID is not made evident to users. There are a number of reported incidents in which the author of a document could be traced by the GUID in the document, even in circumstances where the author had taken exceptional care to maintain their anonymity.

In response to expressed concerns, Microsoft has released a patch for Office 97 SR2 which disables the GUID function, and a utility to remove GUIDs from existing documents.

Concerns about the GUID parallel similar concerns about the potential for abuse of Intel's processor serial number.

Guidelines for Definition of Managed Objects

See "GDMO"

Gyricon

Gyricon is a type of electronic paper (sometimes called **e-paper**) developed at Xerox's Palo Alto Research Center (PARC). The Xerox technology is expected to yield the first complex e-paper products, although other companies (such as Lucent and Philips) are also working on their own versions of e-paper. Gyricon will be used for products such as **e-books**, **electronic newspapers**, portable signs, and foldable, rollable displays.

Gyricon consists of a double sided plastic sheet almost as thin as a standard transparency. Within the sheet are millions of bichromal (two color) balls just .1 mm wide, contained in tiny oil-filled pockets in the material. The balls are rotated by exposure to an electrical charge; they rotate fully to display as black or white, or partially (in response to lower electrical pulses), to display a range of grey shades. Images and text are created by the combined display, and are bi-stable: They remain fixed in position until another electrical pulse is applied to change the orientation of the balls. Data will be downloaded to the ePaper through a wireless connection to a computer or a cell phone.

PARC, in conjunction with 3M, has already manufactured a large roll of Gyricon, to prove the viability of volume production of the ePaper. Xerox has created a subsidiary company, Gyricon Media Inc. to develop and market the technology, which will be seen as early as the end of 2001 in portable, reusable pricing signs for stores that can be changed instantly through a computer link. Nick Sheridan, a senior research fellow at PARC, projects that a Gyricon-based electronic newspaper could be available within the next few years.

H

See “henry”

H.323

H.323 is a standard approved by the International Telecommunication Union (ITU) in 1996 to promote compatibility in **videoconference** transmissions over **IP** networks. H.323 was originally promoted as a way to provide consistency in audio, video and data **packet** transmissions in the event that a local area network (LAN) did not provide guaranteed service quality (QoS). Although it was doubtful at first whether manufacturers would adopt H.323, it is now considered to be the standard for interoperability in audio, video and data transmissions as well as Internet phone and voice-over-IP (VoIP) because it addresses call control and management for both point-to-point and multipoint conferences as well as gateway administration of media traffic, bandwidth and user participation.

H.323, which describes how multimedia communications occur between **terminals**, network equipment and services, is part of a larger group of ITU recommendations for multimedia interoperability called H.3x. The latest of these recommendations, H.248, is a recommendation to provide a single standard for the control of **gateway** devices in multimedia packet transmissions to allow calls to connect from a LAN to a public switched telephone network (PSTN), as well as to other standards-based terminals. This recommendation was announced in August 2000, by the ITU-TU Study Group 16 and the Megaco Working Group of the Internet Engineering Task Force (IETF).

hacker

Hacker is a term used by some to mean “a clever programmer” and by others, especially journalists or their editors, to mean “someone who tries to break into computer systems.”

1) Eric Raymond, compiler of *The New Hacker’s Dictionary*, defines a hacker as a clever programmer. A “good hack” is a clever solution to a programming problem and “hacking” is the act of doing it. Raymond lists five possible characteristics that qualify one as a hacker, which we paraphrase here:

- A person who enjoys learning details of a programming language or system
- A person who enjoys actually doing the programming rather than just theorizing about it
- A person capable of appreciating someone else’s hacking

- A person who picks up programming quickly
- A person who is an expert at a particular programming language or system, as in “UNIX hacker” Raymond deprecates the use of this term for someone who attempts to crack someone else’s system or otherwise uses programming or expert knowledge to act maliciously. He prefers the term **cracker** for this meaning.

2) Journalists or their editors almost universally use hacker to mean someone who attempts to break into computer systems. Typically, this kind of hacker would be a proficient programmer or engineer with sufficient technical knowledge to understand the weak points in a security system. For more on this usage, see **cracker**.

hacktivism

Hacktivism is the act of **hacking**, or breaking into a computer system, for a politically or socially motivated purpose. The individual who performs an act of hacktivism is said to be a *hacktivist*.

A hacktivist uses the same tools and techniques as a **hacker**, but does so in order to disrupt services and bring attention to a political or social cause. For example, one might leave a highly visible message on the home page of a Web site that gets a lot of traffic or which embodies a point-of-view that is being opposed. Or one might launch a **denial-of-service attack** to disrupt traffic to a particular site.

A recent demonstration of hacktivism followed the death of a Chinese airman when his jet fighter collided with a U.S. surveillance plane in April 2001. Chinese and American hacktivists from both countries hacked Web sites and used them as “blackboards” for their statements.

Whether hacktivism is a crime may be debated. Opponents argue that hacktivism causes damage in a forum where there is already ample opportunity for nondisruptive free speech. Others insist that such an act is the equivalent of a protest and is therefore protected as a form of free speech.

hacktivist

See “hacktivism”

HailStorm

Part of Microsoft’s **.Net** initiative, HailStorm is the company’s plan to provide a single place on the Web where any individual user (who pays a fee) may securely store personal and financial information that can be shared with others when desired (for example, to pay for something at an

online store). HailStorm makes use of the Extensible Markup Language (XML) and the Simple Object Access Protocol (SOAP).

The initial set of HailStorm services includes the storing of subscribers' personal information, contacts, locations, profiles, favorite Web sites, and device settings. HailStorm also can provide calendar services and management of inbox items such as e-mail and voice mail. Users pay for all selected services.

An example of a HailStorm service might involve an individual booking an airline flight using an online travel reservation service. With the user's permission, the flight is automatically scheduled into his HailStorm-enabled calendar. If the flight is delayed or canceled, the user is automatically notified. HailStorm services can be accessed from any computer, **smartphone**, personal digital assistant (PDA), or other Internet-connected device.

Microsoft believes that HailStorm offers users online privacy that is not currently available at most Web sites. Today, any information entered into an online form at a Web site becomes the property of that Web site. With HailStorm, the user controls all personal information and decides who gets to use it, how long they may use it, and how they may use it. A user can also revoke access to personal information. Microsoft binds HailStorm licensees to specific terms of use that control how data is used. HailStorm services are expected to be available as a **beta test** in late 2001. Full release is expected in 2002.

Industry commentators and competitors express concerns about Microsoft's ability to keep its users' personal information secure and about the need for an **open** cross-competitor standard as opposed to a proprietary service that becomes a de facto standard.

half-duplex

Half-duplex data transmission means that data can be transmitted in both directions on a signal carrier, but not at the same time. For example, on a local area network using a technology that has half-duplex transmission, one workstation can send data on the line and then immediately receive data on the line from the same direction in which data was just transmitted. Like **full-duplex** transmission, half-duplex transmission implies a bidirectional line (one that can carry data in both directions).

HALO

A HALO (High Altitude Long Operation) aircraft is an aircraft designed to act as a very high altitude receiving and transmitting tower, circling a metropolitan area and providing **broadband** telecommunication service at data rates up to 5 **Mbps** to homes and up to 25 Mbps to business users with dedicated lines. Angel Technologies plans to launch a HALO-based series of metropolitan area networks (MANs). In each city, a single aircraft flying at about 52,000

feet will be able to service home and business users over a 60 mile area. Three aircraft will take turns, each flying an 8-hour shift. Users on the ground will mount a small external antenna outside their home or building. The airplane will link users with each other or with Internet service providers (ISPs) and telephone company offices for connection to networks outside the metropolitan area. Tens or even hundreds of thousands of users can be serviced. Rates are not yet announced.

The aircraft, called the Proteus, is being built in California by Scaled Composites, a subsidiary of Wyman-Gordon Company. It is powered by twin turbofan engines and is designed to have an "efficient high-altitude loiter," to be easy to maneuver, and to sustain flight at altitudes as high as 60,000 feet for 14 hours with a payload of up to 2,000 pounds. Extendible wings allow it to carry a range of payloads. The first "proof of concept" Proteus has been successful in preliminary flight tests.

Unlike the telecommunication **satellite** systems now being developed, a HALO system can be launched for one city at a time. (The HALO aircraft flies at about a tenth of the lowest altitude of the LEO satellite.) An advantage of a high-altitude plane over other wireless solutions is that there is almost no interference. Transmitters will be powered with 40 kilowatts at the 28 and 38 GHz frequency bands. An antenna can receive a signal through trees and during rainstorms. Angel plans to offer three levels of service:

- For home and small business users using dial-up, 1 to 5 Mbps, providing low-cost Internet service, video on demand, and 2-way video conferencing
- For larger businesses using dial-up or dedicated connection, 5 to 12.5 Mbps
- For businesses with dedicated connections, up to 25 Mbps

ham radio

See "amateur radio"

Handheld Device Markup Language

See "HDML"

handheld

A handheld computer is a computer that can conveniently be stored in a pocket (of sufficient size) and used while you're holding it. Today's handheld computers, which are also called personal digital assistants (PDAs), can be divided into those that accept handwriting as input and those with small keyboards. The original handheld that accepted handwriting was Apple's Newton, which was later withdrawn from the market. Today, the most popular handheld that accepts handwritten input is the PalmPilot. Philips, Casio, NEC, Compaq, and other companies make handhelds with small keyboards.

Windows CE and **EPOC** are two of the most widely used **operating systems** in handheld computers.

Handheld computers are typically used for personal information manager (PIM) types of applications: maintaining schedules, keeping names and phone numbers, doing simple calculations, taking notes, and, with a modem, exchanging e-mail and getting information from the Web. Keyboards have tiny keys that take getting used to. Those that handle handwriting also impose constraints and require some learning. Nevertheless, this class of computer is widely sold and appreciated by many users.

Hewlett-Packard has recently introduced the first handheld computer with a color display. A number of companies now combine voice and data telephone service using **cellular telephone** or other **wireless** technologies with the handheld computer in a single device.

handie talkie

A handie talkie, often referred to by its abbreviation, HT, is a handheld, portable two-way radio transceiver. This type of radio is sometimes called a “walkie talkie” or a “handheld.” Handie talkies are popular among **amateur radio** operators, especially on their VHF and UHF bands at 144 and 432 MHz. Handie talkies are widely used by security personnel, military personnel, and police officers. Most HTs are used in conjunction with repeaters for extended range. Some HTs are designed for the 27-MHz **Citizens Band** (CB) radio service.

A typical HT is a rectangular box about the size and weight of an old-fashioned telephone handset. The antenna protrudes from the top end, and consists of a coiled-up element encased in rubber and wound around a flexible rod. This type of antenna, known as a “rubber duck,” is not particularly efficient, but is convenient and rugged. Volume and squelch controls are usually placed next to the antenna. The frequency control knob or buttons are on the top end or the front. A speaker/microphone is contained within the box, as is a battery power supply. A small display shows the frequency or channel, received signal strength, and relative RF output power. The transmitter produces RF power output ranging from about 100 milliwatts (100 mW) to five watts (5 W), depending on the service and the intended use.

Rechargeable nickel-cadmium (NiCd), nickel-metal-hydride (NiMH), or lithium (Li) batteries (see **battery**) are employed as the power supply for a typical HT, with a nominal voltage of 12 to 14 volts DC. Most HTs can be operated while recharging, which is usually done using an adapter connecting the HT to a 117-volt AC utility outlet. Some HTs have adapters that allow recharging from automotive batteries.

handoff

In an ideal **cellular telephone** network, each end user’s telephone set or **modem** (the subscriber’s hardware) is always within range of a base station. The region covered by each base station is known as its **cell**. The size and shape of each cell in a network depends on the nature of the terrain in the region, the number of base stations, and the transmit/receive range of each base station. In theory, the cells in a network overlap; for much of the time, a subscriber’s hardware is within range of more than one base station. The network must decide, from moment to moment, which base station will handle the signals to and from each and every subscriber’s hardware.

Each time a mobile or portable cellular subscriber passes from one cell into another, the network automatically switches coverage responsibility from one base station to another. Each base-station transition, as well as the switching process or sequence itself, is called handoff. In a properly functioning network, handoff occurs smoothly, without gaps in communications and without confusion about which base station should be dealing with the subscriber. Subscribers to a network need not do anything to make handoff take place, nor should they have to think about the process or about which base station is dealing with the signals at any given moment.

handshaking

In telephone communication, handshaking is the exchange of information between two **modems** and the resulting agreement about which **protocol** to use that precedes each telephone connection. You can hear the handshaking in those crunching and other sounds when you make a dial-out call from your computer.

Since the modems at each end of the line may have different capabilities, they need to inform each other and settle on the highest transmission speed they can both use. At higher speeds, the modems have to determine the length of line delays so that echo cancellers can be used properly.

The most common modem standards are briefly described in our **V.xx** page.

Handspring

Handspring is a company that manufactures portable computer/organizer hardware. The principal Handspring product is a handheld computer called the Visor, which is similar to the **Palm** computer and uses the Palm operating system (**Palm OS**). Data can be easily transferred between the Visor and other computers, including Palm handhelds, using **HotSync** technology. Interfacing is possible with Macintosh as well as with IBM-compatible desktop and notebook computers.

The Visor can be tailored to meet the needs of the individual user. It contains an expansion slot called Springboard that allows the addition of modules, each of which is designed for a specific function. The modules are **plug-and-play** and are hot-swappable (they are automatically recognized by the Visor, and they can be exchanged without powering-down or rebooting). Data can be stored and backed up with an optional flash-memory module.

haptics

Haptics (pronounced HAP-tiks) is the science of applying touch (tactile) sensation and control to interaction with computer applications. (The word derives from the Greek *haptēin* meaning "to fasten.") By using special input/output devices (joysticks, data gloves, or other devices), users can receive feedback from computer applications in the form of felt sensations in the hand or other parts of the body. In combination with a visual display, haptics technology can be used to train people for tasks requiring hand-eye coordination, such as surgery and space ship maneuvers. It can also be used for games in which you feel as well as see your interactions with images. For example, you might play tennis with another computer user somewhere else in the world. Both of you can see the moving ball and, using the haptic device, position and swing your tennis racket and feel the impact of the ball.

A number of universities are experimenting with haptics. The Immersion Corporation offers a joystick product that is used in laboratories and in arcade games. Haptics offers an additional dimension to a virtual reality or 3-D environment.

hard disk

A hard disk is part of a unit, often called a "disk drive," "hard drive," or "**hard disk drive**," that stores and provides relatively quick access to large amounts of data on an electromagnetically charged surface or set of surfaces. Today's computers typically come with a hard disk that contains several billion bytes (**gigabytes**) of **storage**.

A hard disk is really a set of stacked "disks," each of which, like phonograph records, has data recorded electromagnetically in concentric circles or "tracks" on the disk. A "head" (something like a phonograph arm but in a relatively fixed position) records (writes) or reads the information on the tracks. Two heads, one on each side of a disk, read or write the data as the disk spins. Each read or write operation requires that data be located, which is an operation called a "seek." (Data already in a **disk cache**, however, will be located more quickly.)

A hard disk/drive unit comes with a set rotation speed varying from 4500 to 7200 rpm. Disk access time is measured in milliseconds. Although the physical location can be identified with cylinder, track, and sector locations, these are actually mapped to a logical block address (**LBA**) that works with the larger address range on today's hard disks.

hard disk drive

In a personal computer, a hard disk drive (HDD) is the mechanism that controls the positioning, reading, and writing of the **hard disk**, which furnishes the largest amount of data **storage** for the PC. Although the hard disk drive (often shortened to "hard drive") and the hard disk are not the same thing, they are packaged as a unit and so either term is sometimes used to refer to the whole unit.

hardcode

In computer programming or text markup, to hardcode (less frequently, *hard code*) is to use an explicit rather than a symbolic name for something that is likely to change at a later time. Such coding is sometimes known as hardcode (noun) and it is more difficult to change if it later becomes necessary. In most programming languages, it is possible to equate a symbol with a particular name (which may also represent a number) value. If the name changes, the symbol stays the same and only the equate line of code needs to be changed to reflect the new name. When the program is recompiled, the new name is picked up wherever the symbol occurs in the code. Although there are search-and-replace tools that can change all occurrences of a given name, program code is very unforgiving in case a small error is introduced, and it is safer to have a single place in which such a change can be made. For this reason, hardcoding is usually a practice to be avoided.

Hardcode is also sometimes used in describing more difficult programming languages such as C or C++ rather than such "softcode" languages as **Visual Basic**.

hardware

Hardware is the physical aspect of computers, telecommunications, and other information technology devices. The term arose as a way to distinguish the "box" and the electronic circuitry and components of a computer from the program you put in it to make it do things. The program came to be known as the **software**.

Hardware implies permanence and invariability. Software or programming can easily be varied. You can put an entirely new program in the hardware and make it create an entirely new experience for the user. You can, however, change the modular configurations that most computers come with by adding new adapters or **card** that extend the computer's capabilities.

Like software, hardware is a collective term. Hardware includes not only the computer proper but also the cables, connectors, power supply units, and peripheral devices such as the keyboard, mouse, audio speakers, and printers.

Hardware is sometimes used as a term collectively describing the physical aspects of telephony and telecommunications network infrastructure.

hardware abstraction layer

1) In computers, a hardware abstraction layer (HAL) is a layer of programming that allows a computer **operating system** to interact with a hardware device at a general or abstract level rather than at a detailed hardware level. **Windows 2000** is one of several operating systems that include a hardware abstraction layer. The hardware abstraction layer can be called from either the operating system's **kernel** or from a **device driver**. In either case, the calling program can interact with the device in a more general way than it would otherwise.

2) "HAL" was the name of the computer that ran the spaceship in Stanley Kubrick and Arthur C. Clarke's film *2001*.

harmonic

A harmonic is a signal or wave whose **frequency** is an integral (whole-number) multiple of the frequency of some reference signal or wave. The term can also refer to the ratio of the frequency of such a signal or wave to the frequency of the reference signal or wave.

Let f represent the main, or fundamental, frequency of an alternating current (AC) signal, **electromagnetic field**, or sound wave. This frequency, usually expressed in **hertz**, is the frequency at which most of the energy is contained, or at which the signal is defined to occur. If the signal is displayed on an oscilloscope, the **waveform** will appear to repeat at a rate corresponding to f Hz.

For a signal whose fundamental frequency is f , the second harmonic has a frequency $2f$, the third harmonic has a frequency of $3f$, and so on. Let w represent the **wavelength** of the signal or wave in a specified medium. The second harmonic has a wavelength of $w/2$, the third harmonic has a wavelength of $w/3$, and so on. Signals occurring at frequencies of $2f$, $4f$, $6f$, etc. are called even harmonics; the signals at frequencies of $3f$, $5f$, $7f$, etc. are called odd harmonics. A signal can, in theory, have infinitely many harmonics.

Nearly all signals contain energy at harmonic frequencies, in addition to the energy at the fundamental frequency. If all the energy in a signal is contained at the fundamental frequency, then that signal is a perfect sine wave. If the signal is not a perfect sine wave, then some energy is contained in the harmonics. Some waveforms contain large amounts of energy at harmonic frequencies. Examples are square waves, sawtooth waves, and triangular waves.

In **wireless** communications and broadcasting, transmitters are designed so they emit a minimum of energy at harmonic frequencies. Normally, a wireless device is intended for use at only one frequency. Signal output at harmonic frequencies can cause interference to other communications or broadcasting. For example, a broadcast signal at 90.5 MHz (in the standard FM band) would have a second harmonic at

181 MHz, a third harmonic at 271.5 MHz, a fourth harmonic at 362 MHz, and so on. Some or all of these harmonic signals could, if strong, disrupt activities in other wireless services.

hash function

See "hashing"

hashing

Hashing is the transformation of a string of **characters** into a usually shorter fixed-length value or key that represents the original string. Hashing is used to index and retrieve items in a **database** because it is faster to find the item using the shorter hashed key than to find it using the original value. It is also used in many **encryption** algorithms.

As a simple example of the using of hashing in databases, a group of people could be arranged in a database like this:

Abernathy, Sara
Epperdingle, Roscoe
Moore, Wilfred
Smith, David

(and many more sorted into alphabetical order)

Each of these names would be the key in the database for that person's data. A database search mechanism would first have to start looking character-by-character across the name for matches until it found the match (or ruled the other entries out). But if each of the names were hashed, it might be possible (depending on the number of names in the database) to generate a unique four-digit key for each name. For example:

7864 Abernathy, Sara
9802 Epperdingle, Roscoe
1990 Moore, Wilfred
8822 Smith, David
(and so forth)

A search for any name would first consist of computing the hash value (using the same hash function used to store the item) and then comparing for a match using that value. It would, in general, be much faster to find a match across four digits, each having only 9 possibilities, than across an unpredictable value length where each character had 26 possibilities.

The hashing **algorithm** is called the *hash function* (and probably the term is derived from the idea that the resulting hash value can be thought of as a "mixed up" version of the represented value). In addition to faster data retrieval, hashing is also used to **encrypt** and decrypt digital signatures (used to authenticate message senders and receivers). The **digital signature** is transformed with the hash function and then both the hashed value (known as a message-digest) and the signature are sent in separate transmissions to the receiver. Using the same hash function as the sender, the receiver derives a message-digest from the signature and compares it with the message-digest it also received. They should be the same.

The hash function is used to index the original value or key and then used later each time the data associated with the value or key is to be retrieved. Thus, hashing is always a one-way operation. There's no need to "reverse engineer" the hash function by analyzing the hashed values. In fact, the ideal hash function can't be derived by such analysis. A good hash function also should not produce the same hash value from two different inputs. If it does, this is known as a *collision*. A hash function that offers an extremely low risk of collision may be considered acceptable.

Here are some relatively simple hash functions that have been used:

- The division-remainder method: The size of the number of items in the table is estimated. That number is then used as a divisor into each original value or key to extract a quotient and a remainder. The remainder is the hashed value. (Since this method is liable to produce a number of collisions, any search mechanism would have to be able to recognize a collision and offer an alternate search mechanism.)
- Folding: This method divides the original value (digits in this case) into several parts, adds the parts together, and then uses the last four digits (or some other arbitrary number of digits that will work) as the hashed value or key.
- Radix transformation: Where the value or key is digital, the number base (or radix) can be changed resulting in a different sequence of digits. (For example, a decimal numbered key could be transformed into a hexadecimal numbered key.) High-order digits could be discarded to fit a hash value of uniform length.
- Digit rearrangement: This is simply taking part of the original value or key such as digits in positions 3 through 6, reversing their order, and then using that sequence of digits as the hash value or key.

A hash function that works well for database storage and retrieval might not work as for cryptographic or error-checking purposes. There are several well-known hash functions used in cryptography. These include the message-digest hash functions MD2, MD4, and MD5, used for hashing digital signatures into a shorter value called a message-digest, and the Secure Hash Algorithm (SHA), a standard algorithm, that makes a larger (60-bit) message digest and is similar to MD4.

HAVi

HAVi is a standard, developed by several leading electronics and computer manufacturers, that allows a number of different home-entertainment and communication devices to operate from a single controller device such as your TV set. The specification uses IEEE 1394 (**FireWire** or **i.LINK**) as the interconnection medium.

With a HAVi-based system, users of home appliances will be able to add new devices without going through complicated installation processes or wading through arcane instruction manuals or help files. Personal computers may be part of a HAVi-based home system, but it will not be necessary for such a system to function.

Here are some examples of how a HAVi system might work:

- You are watching a show on television, and a phone call comes in. You have programmed the television set to automatically mute, so you can carry on the phone conversation without distraction. If you wish, you can carry on the conversation in video-phone mode, and use the television screen as the display.
- Someone rings the buzzer at your front door. You walk over to a wall-based video intercom unit that is playing the five o'clock television news. The screen is switched to a video camera located over the front door so you can see who is there. The audio switches from the television show to a two-way link with the front door.
- You are watching an educational television show, and a scientist uses a word that you do not recognize. You speak the word into a microphone, and an Internet-based dictionary, complete with speech recognition, looks the word up and displays the meaning(s) in the corner of the screen or announces the definition(s) in a synthesized voice.

The HAVi specification will be easy to upgrade. As is the case with popular Web **browsers** today, updates will be available for downloading from the Internet. You might even program the system to automatically download the updates as they become available.

HAVi will be operational across devices from all participating manufacturers. Users will be able to choose their own favorite hardware brands. The video disk recorder (VDR), television set, telephone, home video intercom system, computer (if wanted), and telephone set (with or without video) might all be manufactured by different companies, but they will function seamlessly in the HAVi-based network. When a new device, such as a printer/scanner/fax machine, is installed, the system will configure itself to accommodate it.

Somewhat similar standards for interconnecting devices include Home API (HAPI), **Jini**, Open Services Gateway Initiative (OSGi), Universal PlugnPlay, and Vesa Home Network. HAVi and Vesa are specifically aimed at the home entertainment environment. The other standards are aimed at remote interconnection and make use of Internet protocols.

HCI

Also see **GUI** (graphical user interface).

HCI (human-computer interaction) is the study of how people interact with computers and to what extent computers are or are not developed for successful interaction with human beings. A significant number of major corporations and academic institutions now study HCI. Historically and with some exceptions, computer system developers have not paid much attention to computer ease-of-use. Many computer users today would argue that computer makers are still not paying enough attention to making their products “user-friendly.” However, computer system developers might argue that computers are extremely complex products to design and make and that the demand for the services that a computers can provide has always outdriven the demand for ease-of-use.

One important HCI factor is that different users form different conceptions or mental models about their interactions and have different ways of learning and keeping knowledge and skills (different “cognitive styles” as in, for example, “left-brained” and “right-brained” people). In addition, cultural and national differences play a part. Another consideration in studying or designing HCI is that user interface technology changes rapidly, offering new interaction possibilities to which previous research findings may not apply. Finally, user preferences change as they gradually master new interfaces.

HDD

See “hard disk drive”

HDLC

HDLC (High-level Data Link Control) is a group of **protocols** or rules for transmitting **data** between **network** points (sometimes called **nodes**). In HDLC, data is organized into a unit (called a *frame*) and sent across a network to a destination that verifies its successful arrival. The HDLC protocol also manages the flow or pacing at which data is sent. HDLC is one of the most commonly-used protocols in what is layer 2 of the industry communication reference model called Open Systems Interconnection (**OSI**). (Layer 1 is the detailed physical level that involves actually generating and receiving the electronic signals. Layer 3 is the higher level that has knowledge about the network, including access to **router** tables that indicate where to forward or send data. On sending, programming in layer 3 creates a frame that usually contains source and destination network addresses. HDLC (layer 2) encapsulates the layer 3 frame, adding data link control information to a new, larger frame.)

Now an **ISO** standard, HDLC is based on IBM’s SDLC protocol, which is widely used by IBM’s large customer base in **mainframe** computer environments. In HDLC, the protocol that is essentially SDLC is known as Normal Response Mode (NRM). In Normal Response Mode, a primary station (usually at the mainframe computer) sends data to secondary stations that may be local or may be at remote locations on dedicated leased lines in what is called a multidrop or multipoint network. (This is not the network we usually think of; it’s a nonpublic closed network. In this arrangement, although communication is usually **half-duplex**.)

Variations of HDLC are also used for the public networks that use the **X.25** communications protocol and for **frame relay**, a protocol used in both **and wide area network**, public and private.

In the X.25 version of HDLC, the data frame contains a **packet**. (An X.25 network is one in which packets of data are moved to their destination along routes determined by network conditions as perceived by **routers** and reassembled in the right order at the ultimate destination.) The X.25 version of HDLC uses **peer-to-peer** communication with both ends able to initiate communication on **duplex** links. This mode of HDLC is known as Link Access Procedure Balanced (LAPB).

The following table summarizes the HDLC variations and who uses them.

HDLC SUBSET	USES
NRM (Normal Response Mode)	Multipoint networks that typically use SDLC
LAP (Link Access Procedure)	Early X.25 implementations
LAPB (Link Access Procedure, Balanced)	Current X.25 implementations
LAPD (Link Access Procedure for the ISDN D channel)	ISDN D channel and frame relay
LAPM (Link Access Procedure for Modems)	Error-correcting modems (specified as part of V.42)

HDML

HDML (Handheld Device Markup Language)—often compared to Wireless Markup Language (WML)—is a language that allows the text portions of Web pages to be presented on **cellular telephones** and personal digital assistants (**PDA**s) via **wireless** access. Developed by Unwired Planet, HDML is an open language offered royalty-free. According to UP’s president Chuck Parrish, any programmer with working knowledge of **HTML**, **CGI**, and **SQL** should be able to write a presentation layer using HDML. One major difference between HDML and WML is that WML is **XML**-based, while HDML is not. Another

difference between HDML and WML is that HDML does not allow scripting, while WML allows its own version of **JavaScript**, called WMLScript. Although Unwired Planet has changed their name to Phone.com, specifications for HDML are still available on their Web site in **pdf** format.

HD-ROM

HD-ROM (High-Density—Read Only Memory) is a high-capacity storage technology developed at Norsam Technologies in conjunction with an IBM research group that enables a disc to store hundreds of times as much information as a **CD-ROM**. HD-ROM uses a very narrow, finely-focused particle beam (charged gallium ions) to write data. HD-ROM technology can be used to write data on different types of media, such as metal or other durable materials, to create virtually indestructible storage.

HD-ROM's particle beam, at a size of 50 nanometers, enables a storage capacity of 165 gigabytes on discs the same size as a CD or digital versatile disc (**DVD**). In comparison, CD-ROM uses an 800-nanometer **wavelength laser** beam for a storage capacity of 650 megabytes, and **DVD-ROM** uses a 350-nanometer wavelength laser for a storage capacity of 4.7 gigabytes. HD-ROM was designed to store large databases, such as those required by government agencies, banks, insurance companies, scientific users, and libraries. In addition to the enormous storage capacity, HD-ROM's benefits over traditional archival storage systems (such as magnetic tape and **RAID**) include faster access times, greater durability, and lower costs.

HDSL

HDSL (High bit-rate Digital Subscriber Line), one of the earliest forms of DSL, is used for wideband digital transmission within a corporate site and between the telephone company and a customer. The main characteristic of HDSL is that it is symmetrical: an equal amount of bandwidth is available in both directions. For this reason, the maximum data rate is lower than for Asymmetric DSL (**ADSL**). HDSL can carry as much on a single wire of **twisted-pair** cable as can be carried on a **T1** line in North America or an **E1** line in Europe (2,320 Kbps).

head-end

See "cable head-end"

header

In information technology, a header is, in general, something that goes in front of something else and is usually repeated as a standard part of the units of something else. A header can consist of multiple **fields**, each containing its own value. Here are four common uses:

- 1) In a **document**, a header is some combination of **text** and **images** that can be made to appear at the top of each page when displayed or printed.
- 2) In **e-mail**, the header is the part of a message that describes the originator, the addressee and other recipients, message priority level, and so forth.
- 3) In a computer file, a header may be a field that precedes the main file content and describes the length of the content or other characteristics of the file.
- 4) In a network transmission unit, a header precedes the data or control signals and describes something about the file or transmission unit, such as its length and whether there are other files or transmission units logically or physically associated with this one.

heap

In certain programming languages including C and **Pascal**, a heap is an area of pre-reserved computer **main storage (memory)** that a program **process** can use to store data in some variable amount that won't be known until the program is running. For example, a program may accept different amounts of input from one or more users for processing and then do the processing on all the input data at once. Having a certain amount of heap storage already obtained from the operating system makes it easier for the process to manage storage and is generally faster than asking the **operating system** for storage every time it's needed. The process manages its allocated heap by requesting a "chunk" of the heap (called a *heap block*) when needed, returning the blocks when no longer needed, and doing occasional "garbage collecting," which makes blocks available that are no longer being used and also reorganizes the available space in the heap so that it isn't being wasted in small unused pieces.

The term is apparently inspired by another term, **stack**. A stack is similar to a heap except that the blocks are taken out of storage in a certain order and returned in the same way. In **Pascal**, a *subheap* is a portion of a heap that is treated like a stack.

helical antenna

Also see **satellite**.

A helical antenna is a specialized **antenna** that emits and responds to **electromagnetic fields** with rotating (circular) polarization. These antennas are commonly used at earth-based stations in satellite communications systems. This type of antenna is designed for use with an unbalanced **feed line** such as **coaxial cable**. The center conductor of the cable is connected to the helical element, and the shield of the cable is connected to the reflector.

To the casual observer, a helical antenna appears as one or more "springs" or helices mounted against a flat reflecting screen. The length of the helical element is one **wavelength**

or greater. The reflector is a circular or square metal mesh or sheet whose cross dimension (diameter or edge) measures at least $\frac{3}{4}$ wavelength. The helical element has a radius of $\frac{1}{8}$ to $\frac{1}{4}$ wavelength, and a pitch of $\frac{1}{4}$ to $\frac{1}{2}$ wavelength. The minimum dimensions depend on the lowest **frequency** at which the antenna is to be used. If the helix or reflector is too small (the frequency is too low), the efficiency is severely degraded. Maximum radiation and response occur along the axis of the helix.

Helical antennas are commonly connected together in so-called *bays* of two, four, or occasionally more elements with a common reflector. The entire assembly can be rotated in the horizontal (azimuth) and vertical (elevation) planes, so the system can be aimed toward a particular satellite. If the satellite is not in a geostationary orbit, the azimuth and elevation rotators can be operated by a computerized robot that is programmed to follow the course of the satellite across the sky.

helical scan

Helical scan is a way of recording information onto magnetic tape. It was used to record TV programs in the 1960s, and has been used by several storage vendors (including IBM, Exabyte, StorageTek and others) in their high-end tape-backup products. It's also the same technology used in digital audio tapes (**Digital Audio Tape**).

Helical scan began in the VCR world and uses a spinning read/write head and diagonal tracks. But the recording and playback heads touch the tape, and an IBM scientist concluded in the mid-1990s that helical-scan cartridges can start to deteriorate after being used from 50 to 250 times. For this reason, IBM introduced its follow-on to helical scan in 1995. Called linear technology, it doesn't store as much data as helical scan but the heads don't touch the tape. Helical scan remains a viable option for high-capacity tape backup.

help desk

In a business enterprise, a help desk is a place that a user of information technology can call to get help with a problem. In many companies, a help desk is simply one person with a phone number and a more or less organized idea of how to handle the problems that come in. In larger companies, a help desk may consist of a group of experts using software to help track the status of problems and other special software to help analyze problems (for example, the status of a company's telecommunications network).

Typically, the term is used for centralized help to users within an enterprise. A related term is **call center**, a place that customers call to place orders, track shipments, get help with products, and so forth.

The World Wide Web offers the possibility of a new, relatively inexpensive, and effectively standard user interface to help desks (as well as to call centers) and appears to be encouraging more automation in help desk service.

Some common names for a help desk include: Computer Support Center, IT Response Center, Customer Support Center, IT Solutions Center, Resource Center, Information Center, and Technical Support Center.

henry

The henry (symbolized H) is the International System of Units (SI) unit of **inductance**. Reduced to base SI units, one henry is the equivalent of one kilogram meter squared per second squared per ampere squared ($\text{kg} \cdot \text{m}^2 \cdot \text{s}^{-2} \cdot \text{A}^{-2}$).

In a **circuit** where the **current** is changing at a constant rate of one **ampere** per second (A/s), an inductance of 1 H results in the generation of one **volt** (1 V) of potential difference across an inductor. More rapid current changes produce much greater surges of electromotive force. This is the principle by which a spark coil generates a high and dangerous voltage.

The henry is a large unit of inductance. In audio-frequency (AF) and radio-frequency (RF) applications, units of millihenrys (mH), where $1 \text{ mH} = 10^{-3} \text{ H}$, and microhenrys (μH), where $1 \mu\text{H} = 10^{-6} \text{ H}$, are common. Occasionally, the filter choke in a power supply, or a field coil designed to produce a large voltage upon release of its stored magnetic energy, will be found whose value can be expressed in henrys. In very-high-frequency (VHF), ultra-high-frequency (UHF), and **microwave** devices and systems, units of nanohenrys (nH), where $1 \text{ nH} = 10^{-9} \text{ H}$, and picohenrys (pH), where $1 \text{ pH} = 10^{-12} \text{ H}$, are used.

Also see **capacitor**, **inductor**, **reactance**, and **farad**.

henry per meter

The henry per meter (symbolized H/m) is the unit of magnetic **permeability** in the International System of Units (SI). Reduced to base units in SI, 1 H/m is the equivalent of one kilogram meter per second squared per ampere squared ($\text{kg times m times s}^{-2} \text{ times A}^{-2}$).

Permeability is a characteristic of matter, and is important in the design and construction of electromagnets, inductors, and alternating-current (AC) **transformers**. The permeability of a vacuum (also known as free space) is equal to approximately $1.257 \times 10^{-6} \text{ H/m}$, or 1.257 microhenrys per meter (1.257 $\mu\text{H/m}$).

The henry per meter is a large unit of permeability. Virtually all substances have permeability far less than 1 (unity). However, permeability can also be expressed as the ratio of the number of henrys per meter in a particular substance to

1.257×10^{-6} H/m. In this scheme, free space has a relative permeability of 1, and most substances have relative permeability greater than or equal to this.

Also see **inductor**, **henry**, **magnetic field**, **meter**, **permeability**, and International System of Units (SI).

Herman Hollerith

Born in 1860 in Buffalo, NY, Herman Hollerith was the creator of the Hollerith Electric Tabulating System, the ancestor to computers as we know them today. The system used cards with punched holes to tabulate data. Though first used in 1887 for calculating mortality statistics, Hollerith's punch card system became widely known when it was used to tabulate the U.S. population during the 1890 census.

Hollerith founded the Tabulating Machine Company in 1896. His punch card machine, now fitted with automatic card feeders, was used again in the 1900 census. But by 1910, the U.S. Census Bureau decided to build their own machines because Hollerith was charging too much money for use of his machines.

In 1911, Hollerith's Tabulating Machine Company merged with another machine manufacturer to form Computer Tabulating Recording Company. The new company struggled to gain market share for nearly ten years, and it wasn't until 1920 that it became a leader in the counting machine industry. Hollerith retired in 1921. In 1924, under the direction of Thomas Watson, Sr., the company was renamed International Business Machines Corporation (IBM).

As a primary form of data input for computers, the punch card existed well into the early 1970s before the interactive display terminal began its ascendance. Hollerith died in 1929 in Washington, D.C., and is widely known today as the father of information processing.

hertz

Hertz is a unit of frequency (of change in state or cycle in a sound wave, alternating current, or other cyclical waveform) of one cycle per second. It replaces the earlier term of "cycle per second (cps)."

For example, in the U.S., common house electrical supply is at 60 hertz (meaning the current changes direction or polarity 120 times, or 60 cycles, a second). (In Europe, line frequency is 50 hertz, or 50 cycles per second.) Broadcast transmission is at much higher frequency rates, usually expressed in kilohertz (KHz) or megahertz (MHz).

In acoustic sound, the range of human hearing is from 0 Hz to roughly 20 KHz (depending on many factors, including age and how loud the drummer in your high school rock band played!). The pitch of Middle C on a piano is 263 Hz. Hertz is also used frequently when describing the individual

bands of an audio equalizer. To make that Middle C louder, you could boost other frequencies to around 263 Hz with an equalizer.

The unit of measure is named after Heinrich Hertz, German physicist.

heterogeneous

Heterogeneous (pronounced HEH-tuh-roh-DJEEN-ee-uhs, from the Greek *heteros* or "other" and *genos* or "kind") is the characteristic of containing dissimilar constituents. A common use of this word in information technology is to describe a product as able to contain or be part of a "heterogeneous network," consisting of different manufacturers' products that can "interoperate." Heterogeneous networks are made possible by standards-conforming hardware and software interfaces used in common by different products, thus allowing them to communicate with each other. The Internet itself is an example of a heterogeneous network.

A similar word is *heterogenous*, which means "originating elsewhere."

heuristic

As an adjective, heuristic (pronounced hyu-RIS-tik and from the Greek "heuriskein" meaning "to discover") pertains to the process of knowing by trying rather than by following some preestablished formula. (Heuristic can be contrasted with **algorithmic**.) The term seems to have two usages:

1) Describing an approach to learning by trying without necessarily having an organized hypothesis or way of proving that the results proved or disproved the hypothesis. That is, "seat-of-the-pants" or "trial-by-error" learning.

2) Pertaining to the use of the general knowledge gained by experience, sometimes expressed as "using a rule-of-thumb." (However, heuristic knowledge can be applied to complex as well as simple everyday problems. Human chess players use a heuristic approach.)

As a noun, a heuristic is a specific rule-of-thumb or argument derived from experience.

hexadecimal

Hexadecimal describes a base-16 number system. That is, it describes a numbering system containing 16 sequential numbers as base units (including 0) before adding a new position for the next number. (Note that we're using "16" here as a decimal number to explain a number that would be "10" in hexadecimal.) The hexadecimal numbers are 0-9 and then use the letters A-F. We show the equivalence of binary, decimal, and hexadecimal numbers in the table below.

Hexadecimal is a convenient way to express **binary** numbers in modern computers in which a **byte** is almost always defined as containing eight **binary digits**. When showing the contents of computer storage (for example, when getting a

core dump of storage in order to **debug** a new computer program or when expressing a string of **text characters** or a string of binary values in coding a program or HTML page), one hexadecimal digit can represent the arrangement of four binary digits. Two hexadecimal digits can represent eight binary digits, or a byte.

Binary	Decimal	Hexadecimal
0	0	0
1	1	1
10	2	2
11	3	3
100	4	4
101	5	5
110	6	6
111	7	7
1000	8	8
1001	9	9
1010	10	A
1011	11	B
1100	12	C
1101	13	D
1110	14	E
1111	15	F
10000	16	10
10001	17	11
etc	etc	etc

HFC

See “hybrid fiber coaxial network”

hiccup

In information technology, hiccup is an informal term for a non-recurring problem of indeterminate cause that usually does not cause a significant disruption of work or activity. A hiccup might be due to a transient power level change, a program bug that is only encountered under very rare circumstances, or something else. Unlike hiccups in human beings, a hiccup in a computer or a network tends not to be followed by additional hiccups. If it does, then it may rise to the level of a “problem.”

A hiccup is similar to a **glitch** in terms of its temporariness, but is usually less serious.

High Level Assembler

High Level Assembler (HLASM) is IBM’s **assembler** programming language and the assembler itself for the IBM OS/390, MVS, VM, and VSE operating systems. Released in June 1992, HLASM was the first new assembler language from IBM in twenty years. Version 4 was released in September 2000.

In common with other assembler (sometimes known as assembly) programs, HLASM translates basic computer instructions (such as Load, for example, which instructs the processor to move data from memory to a register) to **machine code**, the **binary** information that is all that computers understand.

HLASM replaced IBM’s earlier assembler programs, Assembler H Version 2, Assembler XF, DOS/VSE, and VSE/AF. IBM claims that HLASM features a number of improvements over other assembler programs. HLASM includes support for existing applications through such measures as extensions to earlier IBM assemblers. Automation of common tasks and cross-reference features was included to make programming and administrative tasks easier and less time-consuming, while improved diagnostics were developed to find common, but hard-to-find coding errors more quickly. The HLASM Toolkit, an optional feature, includes additional development, diagnosis, and recovery tools.

High Performance File System

HPFS (High Performance File System) is the **file system** introduced with IBM’s OS/2 Version 1.2. HPFS is noted for handling large files (2 **gigabytes**) across multiple hard disk volumes (addressable up to 2 **terabyte**) and long file names (up to 256 bytes). OS/2 was designed to get around several limitations at the time in MS-DOS, among them its eight-character name. HPFS uses a centrally located **root directory** and B-tree lookup to speed access. HPFS can coexist with the MS-DOS file system, File Allocation Table (**file allocation table**), or run independently.

Among the benefits of HPFS:

- Contiguous storage of extended attributes (without the EA DATA.SF file used by FAT)
- Resistance to file fragmentation
- Small cluster size
- Support for larger file storage devices (up to 512 GB)
- Speedier disk operation

Among the drawbacks:

- Requires more system memory

- HPFS partitions are not visible to MS-DOS, so if you need to boot from a floppy disk, it could be inconvenient.
- Native DOS needs a special utility (Partition Magic from PowerQuest) to access a HPFS partition

High Performance Storage System

High-Performance Parallel Interface

See "HIPPI"

High-Speed Circuit-Switched Data

High-Speed Circuit-Switched Data (HSCSD) is **circuit-switched wireless** data transmission for mobile users at data rates up to 38.4 Kbps, four times faster than the standard data rates of the Global System for Mobile (GSM) communication standard in 1999. HSCSD is comparable to the speed of many computer **modems** that communicate with today's fixed telephone networks.

HSCSD is an evolutionary technology on the way to Universal Mobile Telecommunications Service (UMTS).

High-Speed Serial Interface

High-Speed Serial Interface (HSSI) is a short-distance communications **interface** that is commonly used to interconnect routing and switching devices on local area networks (LANs) with the higher-speed lines of a wide area network (WAN). HSSI is used between devices that are within fifty feet of each other and achieves data rates up to 52 Mbps. Typically, HSSI is used to connect a LAN **router** to a T-3 line. HSSI can be used to interconnect devices on **token ring** and **Ethernet** LANs with devices that operate at Synchronous Optical Network (SONET) **OC-1** speeds or on T-3 lines. HSSI is also used for host-to-host linking, image processing, and disaster recovery applications.

Like ISDN and DSL, HSSI operates at the **physical layer** of a network, using the standard Open Systems Interconnection (OSI) model. The electrical connection uses a 50-pin connector. The HSSI transmission technology uses *differential emitter-coupled logic (ECL)*. (ECL is a circuit design in which two **transistor** emitters are connected to a **resistor** that is switched between the emitters, producing high bit rates.) HSSI uses gapped timing. Gapped timing allows a Data Communications Equipment (DCE) device to control the flow of data being transmitted from a Data Terminating Equipment (DTE) device such as a terminal or computer by adjusting the **clock speed** or deleting clock impulses.

For diagnosing problems, HSSI offers four **loopback** tests. The first loopback tests the cable by looping the signal back after it reaches the DTE port. The second and third loopbacks test the line ports of the local DCE and the remote DTE. The fourth tests the DTE's DCE port. HSSI requires two control signals ("DTE available" and "DCE available") before the data circuit is valid.

The HSSI cable uses the same number of pins and wires as a SCSI-2 cable, but uses the HSSI electrical interface. It is not recommended to use a SCSI-2 cable with an HSSI interface.

hijacking

Hijacking is a type of network security attack in which the attacker takes control of a communication—just as an airplane hijacker takes control of a flight—between two entities and masquerades as one of them. In one type of hijacking (also known as a **man in the middle** attack), the perpetrator takes control of an established connection while it is in progress. The attacker intercepts messages in a public key exchange and then retransmits them, substituting their own **public key** for the requested one, so that the two original parties still appear to be communicating with each other directly. The attacker uses a program that appears to be the server to the client and appears to be the client to the server. This attack may be used simply to gain access to the messages, or to enable the attacker to modify them before retransmitting them.

Hijacking is also used to make it appear that one or more Web sites have been taken over. There are two different types of domain name system (DNS) hijacking. In one, the attacker gains access to DNS records on a server and modifies them so that requests for the genuine Web page will be redirected elsewhere—usually to a fake page that the attacker has created. This gives the impression to the viewer that the Web site has been compromised, when in fact, only a server has been. In February 2000, an attacker hijacked RSA Security's Web site by gaining access to a DNS server that was not controlled by RSA. By modifying DNS records, the attacker diverted requests to a **spoof** Web site. It appeared to users that an attacker had gained access to the actual RSA Web site data and changed it—a serious problem for a security enterprise. This type of hijacking is difficult to prevent, because administrators control only their own DNS records, and have no control over **upstream** DNS servers. In the second type of DNS hijack, the attacker spoofs valid e-mail accounts and floods the inboxes of the technical and administrative contacts. This type of attack can be prevented by using **authentication** for **InterNIC** records.

In another type of Web site hijack, the perpetrator simply registers a **domain name** similar enough to a legitimate one that users are likely to type it, either by mistaking the actual name or through a typo. This type of hijack is currently being employed to send many unwary citizens to porn sites when they were attempting to visit official Web sites such as Amazon, Dow Jones, and the White House, among others.

HiperLAN

HiperLAN is a set of wireless local area network (WLAN) communication standards primarily used in European countries. There are two specifications: HiperLAN/1 and HiperLAN/2. Both have been adopted by the European Telecommunications Standards Institute (ETSI).

The HiperLAN standards provide features and capabilities similar to those of the IEEE 802.11 wireless local area network (LAN) standards, used in the U.S. and other adopting countries. HiperLAN/1 provides communications at up to 20 Mbps in the 5-GHz range of the radio frequency (RF) spectrum. HiperLAN/2 operates at up to 54 Mbps in the same RF band. HiperLAN/2 is compatible with 3G (third-generation) WLAN systems for sending and receiving data, images, and voice communications. HiperLAN/2 has the potential, and is intended, for implementation worldwide in conjunction with similar systems in the 5-GHz RF band.

Also see 802.11.

HIPPI

HIPPI (High-Performance Parallel Interface) is a standard point-to-point protocol for transmitting large amounts of data at up to billions of bits per second over relatively short distances, mainly on local area networks (LANs). The proponents of HIPPI believe that its use can make computers, interconnected storage devices, and other resources on a local area network function as though they were all within a single supercomputer. (One firm has coined the term *SuperLAN* for this idea.) HIPPI is considered an ideal technology for the transfer of “big data,” such as data warehouse updating, audio and video streams, and data backup within a range up to 10 kilometers.

HIPPI uses a point-to-point link. The original HIPPI standard specifies data transfer at 800 Mbps with a 32-bit data bus or 1600 Mbps with a 64-bit data bus. Basic HIPPI uses 50 twisted pair copper wires with a maximum range limited to 25 meters. Data is sent in bursts of 1024 or 2048 bytes on a unidirectional channel. Full duplex can be achieved using two channels. An important part of HIPPI is the use of a network switch that will allow data to be forwarded in the network with minimal processing (the switches are called *nonblocking crossbar switches*). Error detection is provided, but error correction is left to a higher protocol level. HIPPI packets can be encapsulated and sent over ATM and Fibre Channel networks.

Serial HIPPI, a later version of HIPPI, is designed for networks up to 10 kilometers using optical fiber cable. An even faster technology is HIPPI-6400, which promises up to 6.4 Gbps. (See the table that follows.)

HIPPI defines interfaces at the Physical layer (layer 1) and for part of the Data-Link Control (DLC) (layer 2) levels of the Open Systems Interconnection (OSI) communications

model. In addition to the standard HIPPI specification, there are working papers for proposed standards for related aspects of using HIPPI at the application level.

The following table summarizes HIPPI technologies.

HIPPI Technology	Speed	Maximum Distance	Physical Medium
HIPPI-800	800 Mbps (100 megabytes per second)	25 meters	One 50-pair twisted pair copper wire
HIPPI-1600	1600 Mbps (200 Mbytes per second)	25 meters	Two 50-pair twisted pair copper wire
HIPPI-800 Serial	800 Mbps	1 kilometer with... 10 kilometers with...	multimode fiber optical fiber single mode fiber optical fiber
HIPPI-1600 Serial	1600 Mbps	1 kilometer with... 10 kilometers with...	multimode fiber optical fiber single mode fiber optical fiber
HIPPI-6400	6.4 Gbps	50 meters	twisted pair copper wire
HIPPI-6400	6.4 Gbps	1 kilometer	optical fiber

history

In a Web browser, the history is a detailed list of Web sites the computer has visited which remains in a computer’s memory for a pre-determined number of days. (The number of days the computer retains its history can be set in the browser’s preferences.) History can be used to backtrack where you have gone on the Web; the list of Web sites in a browser’s history can be viewed by date, time of day, title, address (URL), alphabetical order, or number of repeat visits. Many parent groups advocate checking the history of a family computer to monitor where children have gone online. Internet Explorer history can be viewed by clicking on the History icon (which resembles a sun dial) in the browser toolbar. Netscape history can be viewed by clicking on the word “Communicator” followed by “Tools” and then “History.”

hit

A hit is a single file request in the access log of a Web server. A request for an HTML page with three graphic images will result in four hits in the log: one for the HTML text file and one for each of the graphic image files. While a hit is a meaningful measure of how much traffic a server handles, it can be a misleading indicator of how many pages are being

looked at. Instead, advertising agencies and their clients look at the number of pages delivered and ad **impressions** or views.

HLASM

See "High Level Assembler"

HOLAP

See "hybrid online analytical processing"

hole

In physics, a hole is an electric charge carrier with a positive charge, equal in magnitude but opposite in **polarity** to the charge on the **electron**. Holes and electrons are the two types of charge carriers responsible for **current** in **semiconductor** materials.

A hole is the absence of an electron in a particular place in an **atom**. Although it is not a physical particle in the same sense as an electron, a hole can be passed from atom to atom in a semiconductor material. Electrons orbit the nucleus at defined energy levels called *bands* or *shells*. A hole forms in an atom when an electron moves from the so-called *valence band* (the shell outside the closed shells that is partially or completely filled with electrons) into the *conduction band* (the outer "cloud" from which electrons most easily escape from, or are accepted by, the atom).

Both electrons and holes are present in any semiconductor substance. Electrons flow from minus to plus, and holes "flow" from plus to minus. The more abundant charge carriers are called *majority carriers*; the less abundant are called *minority carriers*. In N-type semiconductor material, electrons are the majority carriers and holes are the minority carriers. In P-type semiconductor material, the opposite is true.

In the processing of semiconductors, the number of charge carriers can be increased by a process known as *doping*, which consists of adding minute amounts of elements called *impurities*. Certain impurities, when added to a semiconducting element such as silicon, increase the number of electrons and produce an N-type material; other impurities increase the number of holes and produce a P-type material. Both N-type and P-type material are important in the manufacture of solid-state electronic components.

hologram

A hologram (pronounced HOL-o-gram) is a three-dimensional image, created with photographic projection. The term is taken from the Greek words *holos* (whole) and *gramma* (message). Unlike **3-D** or **virtual reality** on a two-dimensional computer display, a hologram is a truly three-dimensional and free-standing image that does not simulate spatial depth or require a special viewing device.

Theoretically, holograms could someday be transmitted electronically to a special display device in your home and business.

The theory of holography was developed by Dennis Gabor in 1947. The development of laser technology made holography possible.

holographic storage

Holographic storage is computer storage that uses laser beams to store computer-generated data in three dimensions. The goal is to store a lot of data in a little bit of space.

Perhaps you have a bank credit card containing a logo in the form of a **hologram**. The idea is to use this type of technology to store computer information.

Although no one has yet mass-commercialized this technology, many vendors—including Lucent and IBM—are working on it. Prototypes of holographic storage devices can store at least 12 times the amount of information on today's largest magnetic hard disk drives, with input/output rates more than 10 times faster than what is possible today.

home network

A home network is two or more computers interconnected to form a local area network (**LAN**) within the home. In the U.S., for example, it is estimated that 15 million homes have more than one computer. A home network allows computer owners to interconnect multiple computers so that each can share files, programs, printers, other peripheral devices, and Internet access with other computers, reducing the need for redundant equipment and, in general, making everything easier to use. For example, if you have an older computer without a CD-ROM, you can access your newer computer's CD-ROM instead of purchasing one for your older computer. Sharing files across a home network is also easier than copying a file to a floppy and running to the other computer to use the file. A new trend, sometimes referred to as an *intelligent network*, extends the home network to include controls for the home ambient environment, security systems, and kitchen devices. In general, a home network is distinguished from a small office-home office (**SOHO**) network only by its more general purpose and possibly by the kinds of devices that are interconnected.

Before deciding what kind of home network you want, you must ask yourself if it bothers you to drill holes and run wire throughout your house? Do you mind opening your computer and installing network cards? Are your computers in the same room? What is your budget for a home network? Do you mind paying someone to come in and do the setup for you?

There are five types of home networks, two that use wire connections and three that use **wireless** connections:

- **Direct cable connection:** This allows you to connect both computers with a \$10 **null modem** that plugs into both computers' **serial, parallel, or Universal Serial Bus port**. You simply configure the Windows 9x/NT Direct Cable Connection feature and you're ready to go. You lose your printer's parallel port if you use a parallel port connection. USB is faster than both serial and parallel, but you must make sure you are using Windows 95B or Windows 98 when using a USB network. This is a possible choice when two computers are in the same room.
- **Traditional Ethernet:** A **peer-to-peer Ethernet** network requires installing network interface cards (NIC) inside each computer and interconnecting them with a **coaxial cable** or a **twisted pair** cable. You have to install **driver** and configure Windows 9x/NT. The drawback to an Ethernet network is the difficulty of hardware installation. Will your computers recognize the new cards? If your computers have several cards installed already, you might run into hardware conflicts. This type of network is suitable for use with two to twelve computers. You can have your computers scattered throughout your house, but you will have to wire each room that has a computer. Beginning cost of an Ethernet network is \$100.
- **AC network:** An AC (alternating current) network is a possibility when computers are in different locations in your house. You don't need to drill any holes or wire any rooms. You simply plug one end of an adapter into the parallel port of your computer and plug the other end into an outlet. You do the same for each computer. Your data is transmitted through the power lines. You can have a ready-made network anywhere in the house at any time. When purchasing the equipment and software for your AC network, make sure it includes extra outlet strips and an adapter for your printer. The software setup can be difficult for AC networks. The cost of an AC network is \$200 for two computers.
- **Phonenumber network** This type of wireless network was developed by the Home Phonenumber Networking Alliance (HomePNA) to offer an easy and inexpensive (starting at \$150 for two computers) solution that uses existing phone lines. For example, Action Tec's ActionLink Home Networking Kit provides **PCI card** that share a single **registered jack** with your **modem** and telephone. The HomePNA technology is designed to not interfere with your voice and data transmissions. This means that you can talk on the phone and use your Internet connection at the same time without any noticeable decrease in modem speed. A phonenumber network does require you to install PCI cards and software drivers. The data transfer rate of a phonenumber network is 10 **Mbps**.
- **Radio Free (RF) network:** This type of wireless network uses radio frequency (RF) waves to transmit through walls and floors up to 800 feet. The only hardware is a

special card inserted into each computer or a **transceiver** plugged into each computer's parallel port. If you purchase an RF network that uses transceivers, make sure equipment is included for connecting your printer. The problem with an RF network is interference from other wireless communication devices. Some RF network packages promise no interference from other wireless devices. RF networks start at \$100.

A number of companies offer approaches to an *intelligent network* in the home. For example, IBM is partnering with home developers to equip new houses with Home Director Model 200, which includes the distribution of video and satellite connections throughout your house, using your DVD player in the living room to watch a movie in your bedroom, automatically turning on and off your lights, and lowering your thermostat at night.

home page

1) For a Web user, the home page is the first Web **page** that is displayed after starting a Web **browser** like Netscape's Navigator or Microsoft's Internet Explorer. The browser is usually preset so that the home page is the first page of the browser manufacturer. However, you can set it to open to any **Web site**. For example, you can specify "http://www.yahoo.com" or "http://what.is.com" as your home page. You can also specify that there be no home page (a blank space will be displayed) in which case you choose the first page from your bookmark list or enter a Web address.

2) For a Web site developer, a home page is the first page presented when a user selects a **site** or **presence** on the World Wide Web. The usual address for a Web site is the home page address, although you can enter the address (**Uniform Resource Locator**) of any page and have that page sent to you.

Home Phonenumber Networking Alliance

The HPNA (Home Phonenumber Networking Alliance) is an industry group that promotes standards for using existing phone lines and jacks to interconnect computers within a home. The HPNA's **HomePNA** standard is one of several leading technologies for **home network**.

HPNA's approach is one of several competing home networking approaches. Others include **Ethernet**, the powerline protocol, or the **Bluetooth** standard. Ethernet is a widely-used standard for a local area network (**LAN**) that requires each computer to be equipped with an interface card and the installation of thicker cabling. Powerline is a slower data transmission method that uses the home's electrical wiring. Bluetooth uses wireless technology to transmit data between devices within a 30-foot range. In addition to HomePNA, there are other proprietary approaches to home networks using existing phone lines.

The Home Phonline Networking Alliance is a consortium with over 100 members, including 3Com, AT&T Wireless, IBM, Intel, Compaq, Lucent Technologies, and Hewlett-Packard.

homecam

See “cam”

HomePNA

HomePNA is an industry standard for interconnecting computers within a home using existing telephone lines and **registered jacks**. Using HomePNA, multiple computer users in a home can share a single Internet connection, open or copy files from different computers, share printers, and play multiuser computer games. The latest version, HomePNA 2.0, allows data transmission at a rate of 10 **Mbps** over a standard telephone line's home wiring system using the **Ethernet CSMA/CD** framing and transmission protocol. HomePNA can be used without interrupting normal voice or fax services. One user can talk on the phone at the same time other users are sharing the same line to access the Web or share other computer resources. A Quality of Service (**QoS**) feature assigns higher-level priorities to applications that are latency-sensitive like packetized voice and streaming audio and video. The **home network** standard is sponsored by members of the Home Phonline Networking Alliance (**HPNA**).

The shared phone line approach is one of several home network approaches. Others include the regular Ethernet local area network, the powerline protocol, or the **Bluetooth** standard. Ethernet is a widely-used standard for a local area network (**LAN**) that ordinarily requires each computer to be equipped with an interface card, connected to a **hub**, and sometimes the use of thicker cabling. (HomePNA uses the Ethernet line protocol with existing phone cabling.) Powerline is a slower data transmission method that uses the home's electrical wiring. Bluetooth uses wireless technology to transmit data between devices within a 30-foot range. In addition to HomePNA, there are other proprietary approaches to home networks using existing phone lines.

HomeRF

HomeRF (for *home radio frequency*) is a home networking standard developed by Proxim Inc. that combines the **802.11b** and Digital Enhanced Cordless Telecommunication (**DECT**) portable phone standards into a single system. HomeRF uses a **frequency-hopping** technique to deliver speeds of up to 1.6 **Mbps** over distances of up to 150 ft—too short a range for most business applications, but suitable for the home market that it was specifically developed for.

HomeRF is one of two standards currently vying for the wireless home network market share. The other main contender, **Wi-Fi** uses a direct sequence spread spectrum (**DSSS**) transmission method to deliver speeds of up to 11

Mbps. HomeRF is said to have better mechanisms in place to deal with interference (from microwave ovens, for example) and to handle voice, video, and audio data better than Wi-Fi. Nevertheless, Wi-Fi is significantly faster than HomeRF—albeit more expensive as well. Wi-Fi products have already become fairly well established in corporate wide area networks (**WANs**), which tend to support the older standard for home networks, since consumers tend to prefer to use the same technologies in both home and work settings. Although industry support is split between the two technologies, a number of companies (such as IBM and Proxim itself) have begun to back both standards.

honey pot

A honey pot is a computer system on the Internet that is expressly set up to attract and “trap” people who attempt to penetrate other people's computer systems. (This includes the **hacker**, **cracker**, and **script kiddy**.) To set up a honey pot, it is recommended that you:

- Install the **operating system** without **patches** installed and using typical defaults and options
- Make sure that there is no data on the system that cannot safely be destroyed
- Add the application that is designed to record the activities of the invader

Maintaining a honey pot is said to require a considerable amount of attention and may offer as its highest value nothing more than a learning experience (that is, you may not catch any hackers).

hook

In programming, a hook is a place and usually an interface provided in packaged code that allows a programmer to insert customized programming. For example, a programmer might want to provide code that analyzed how often a particular logic path was taken within a program. Or a programmer might want to insert an additional capability. Typically, hooks are provided for a stated purpose and are documented for the programmer.

Some writers use hook to also mean the program that gets inserted.

hoot and holler

See “hoot-n-holler”

hoot-n-holler

In telecommunications, a hoot-n-holler is a dedicated “always on” connection used for two-way business-to-business voice communication. Hoot-n-holler networks evolved from a type of crude point-to-point plain old telephone system (**POTS**) used by small businesses with large inventories in the mid-1900's. A plumbing supply

company in the 1950's, for instance, might use a full-duplex, transmit-and-receive device commonly called a "squawk box" or "shout down" to allow the front desk person to have two-way communication with the warehouse supervisor over a dedicated open phone line without having to pick up a receiver or dial a phone. Hoot-n-holler found a home at brokerage firms in the 1960's, where it became more sophisticated and grew into the speakerphone and conference-call technology many businesses use today.

Hoot-n-holler is still used extensively in the financial community to share market updates and trading orders and is also used at news agencies, weather bureaus, transportation providers, and in manufacturing work environments. According to Cisco Systems, some larger financial firms budget 2–3 million dollars a year just for distribution of their hoot-n-holler feeds to remote branch offices. Voice over IP (VoIP) hoot-n-holler is slowly gaining popularity and is being promoted as a cost-effective solution for "party-line" communication because it still allows users in a hoot-n-holler network to talk simultaneously if they want to, but also allows any idle bandwidth to be reclaimed and used by data applications.

hop

1) In a packet-switching network, a hop is the trip a **data packet** takes from one **router** or intermediate point to another in the network. On the Internet (or a network that uses TCP/IP), the number of hops a packet has taken toward its destination (called the "hop count") is kept in the packet header. A packet with an exceedingly large hop count is discarded.

2) Using Cellular Digital Packet Data (CDPD), a hop is a switch to another radio frequency (RF) channel.

Hopper, Grace

See "Grace Hopper"

horn antenna

A horn antenna is used for the transmission and reception of **microwave** signals. It derives its name from the characteristic flared appearance. The flared portion can be square, rectangular, or conical. The maximum radiation and response corresponds with the axis of the horn. In this respect, the antenna resembles an acoustic horn. It is usually fed with a **waveguide**.

In order to function properly, a horn antenna must be a certain minimum size relative to the **wavelength** of the incoming or outgoing **electromagnetic field**. If the horn is too small or the wavelength is too large (the **frequency** is too low), the antenna will not work efficiently.

Horn antennas are commonly used as the active element in a **dish antenna**. The horn is pointed toward the center of the dish reflector. The use of a horn, rather than a **dipole antenna** or any other type of antenna, at the focal point of the dish minimizes loss of energy (leakage) around the edges of the dish reflector. It also minimizes the response of the antenna to unwanted signals not in the favored direction of the dish.

Horn antennas are used all by themselves in short-range radar systems, particularly those used by law-enforcement personnel to measure the speeds of approaching or retreating vehicles.

host

The term "host" is used in several contexts, in each of which it has a slightly different meaning:

1) In Internet protocol specifications, the term "host" means any computer that has full two-way access to other computers on the Internet. A host has a specific "local or host number" that, together with the network number, forms its unique **IP address**. If you use **Point-to-Point Protocol** to get access to your access provider, you have a unique IP address for the duration of any connection you make to the Internet and your computer is a host for that period. In this context, a "host" is a **node** in a network.

2) For companies or individuals with a **Web site**, a host is a computer with a **Web server** that serves the pages for one or more Web sites. A host can also be the company that provides that service, which is known as **hosting**.

3) In IBM and perhaps other mainframe computer environments, a host is a mainframe computer (which is now usually referred to as a "large server"). In this context, the mainframe has intelligent or "dumb" workstations attached to it that use it as a host provider of services. (This does not mean that the host only has "servers" and the workstations only have "clients." The server/client relationship is a programming model independent of this contextual usage of "host.")

4) In other contexts, the term generally means a device or program that provides services to some smaller or less capable device or program.

hosting

Hosting (also known as *Web site hosting*, *Web hosting*, and *Webhosting*) is the business of housing, serving, and maintaining files for one or more **Web sites**. More important than the computer space that is provided for Web site files is the fast connection to the Internet. Most hosting services offer connections on **T-carrier system** lines. Typically, an individual business hosting its own site would require a similar connection and it would be expensive. Using a hosting service lets many companies share the cost of a fast Internet connection for serving files.

A number of Internet access providers, such as America Online, offer subscribers free space for a small Web site that is hosted by one of their computers. Geocities is a Web site that offers registered visitors similar free space for a Web site. While these services are free, they are also very basic.

A number of hosting companies describe their services as **virtual hosting**. Virtual hosting usually implies that their services will be transparent and that each Web site will have its own **domain name** and set of e-mail addresses. In most usages, *hosting* and *virtual hosting* are synonyms. Some hosting companies let you have your own **virtual server**, the appearance that you are controlling a **server** that is dedicated entirely to your site.

Dedicated hosting is the provision of a **dedicated server** machine that is dedicated to the traffic to your Web site. Only very busy sites require dedicated hosting. Many companies purchase their own servers and place them on a site that provides fast access to the Internet. This practice is called **colocation**.

hosting reseller

See "reseller hosting"

hot fix

See "hotfix"

hot key

A hot key is a key or a combination of keys on a computer **keyboard** that, when pressed at one time, performs a task (such as starting an application) more quickly than by using a **mouse** or other input device. Hot keys are sometimes called shortcut keys. Hot keys are supported by many **operating system** and applications.

The specific task performed by a particular hot key varies by operating system or application. However, there are commonly-used hot keys. For example, pressing the F1 key in any application running Windows usually brings up a help menu. The "Alt + F4" combination results in closing the

current application or, if no application is open, shutting down Windows. To find out which hot keys are used in an application, search the index in that application's help menu using the words "hot keys" or "shortcut keys."

The "F" or **function key** that come on most computer keyboards can be viewed as a built-in set of hot keys or potential hot keys whose use is determined by the operating system or the current application. Some operating systems or applications allow certain hot keys to be set up to perform a task specified by the user or to start a specific application. For example, a user could set up one hot key to start a music compact disk (CD) and another to adjust the speaker volume.

Microsoft's sales literature refers to hot keys as though they are keys separate from function keys.

hot site and cold site

A hot site is a commercial disaster recovery service that allows a business to continue computer and network operations in the event of a computer or equipment disaster. For example, if an enterprise's data processing center becomes inoperable, that enterprise can move all data processing operations to a hot site. A hot site has all the equipment needed for the enterprise to continue operation, including office space and furniture, telephone jacks, and computer equipment.

A cold site is a similar type of disaster recovery service that provides office space, but the customer provides and installs all the equipment needed to continue operations. A cold site is less expensive, but it takes longer to get an enterprise in full operation after the disaster.

Typically, a business has an annual contract with a company that offers hot and cold site services with a monthly service charge. Some disaster recovery services offer **backup** services so that all company data is available regardless of whether a hot site or cold site is used. If an enterprise must use a hot or cold site, there are usually daily fees and other incidental fees in addition to the basic service charge.

Hot Standby Router Protocol

Hot Standby Router Protocol (HSRP) is a routing **protocol** that allows **host** computers on the Internet to use multiple **routers** that act as a single virtual router, maintaining connectivity even if the first **hop** router fails, because other routers are on "hot standby"—ready to go. Configured on Cisco routers running the Internet Protocol (**IP**) over **Ethernet**, Fiber Distributed-Data Interface (**FDDI**), and **token ring** local area networks (**LANs**), HSRP provides automatic router backup. The protocol is fully compatible with Novell's Internetwork Packet Exchange (**IPX**), **AppleTalk**, and Banyan **VINES**, and (in some configurations) with Xerox Network Systems (**XNS**) and **DECnet**.

Developed by **Cisco** and specified in **IETF** Request for Comments (**RFC**) 2281, **HSRP** ensures that only a single router (called the *active router*) is forwarding **packets** on behalf of the virtual router at any given time. A standby router is chosen to be ready to become the active router, in the event that the current active router fails. **HSRP** defines a mechanism used to determine active and standby routers by referring to their **IP addresses**. Once these are determined, the failure of an active router will not cause any significant interruption of connectivity.

On any given LAN, there may be multiple, possibly overlapping, hot standby groups, each with a single Media Access Control (**MAC**) address and IP address; the IP address should belong to the primary **subnet**, but must be different from any actual or virtual addresses allocated to any routers or hosts on the network.

hot swap

A hot swap is the replacement of a hard drive, CD-ROM drive, power supply, or other device with a similar device while the computer system using it remains in operation. The replacement can be because of a device failure or, for storage devices, to substitute other data.

Hot swapping works by providing a rack or enclosure for the device that provides an appearance to the computer's **bus** or I/O controller that the device is still there while it's being removed and replaced with another device. A hot swap arrangement is sometimes provided where multiple devices are shared on a local area network. Hot swap arrangements are sold for both **SCSI** and **IDE** hard drives. Hot swap versions of a redundant array of independent devices (**RAID**) are also available.

hotfix

In Microsoft products, a hotfix is code (sometimes called a **patch**) that fixes a **bug** in the product. Users of the products are typically notified or can obtain information about current hotfixes at Microsoft's Web site and download the hotfixes they wish to apply. Hotfixes are sometimes packaged as a set of fixes called a combined hotfix or a **service pack**.

Quick fix engineering (**QFE**) is a newer Microsoft term for a hotfix.

HotSync

HotSync is the registered trade name for a sophisticated method of linking between a **Palm** handheld computer and a more substantial notebook, desktop, or other computer. Such a link can be done using a so-called HotSync cable, or using a wireless connection. If the portable computer and the larger machine are in the same room, the link can use infrared radiation (**IR**).

Direct linking between computers eliminates the need for cumbersome disks or tapes when data must be copied from one **hard drive** to another. But the versatility of the scheme goes beyond simple data transfer. In a network, direct linking allows each portable computer to take advantage of the resources of the whole system, and also allows communication between or among end users.

HP 9000

The HP 9000 is a line of **UNIX**-based business **servers** from **Hewlett-Packard** (HP) with server models that span **enterprise** applications from the "entry-level" (branch or department-level computers, Web hosting servers, and so forth) through the **midrange** with needs for handling advanced enterprise resource planning (**ERP**) and analytical customer resource management (**CRM**) up to its high-end servers for very computing-intensive applications. Within the entry-level, midrange, and high-end categories, a customer can choose one of several "classes" of server. In all cases, the **operating system** is **HP-UX**.

The HP 9000 uses HP's 8600 processor with **PA-RISC** architecture. At the high end, HP offers **SuperDome**, a product that consists of up to 64 HP 9000 processors that can do **parallel processing**. The customer can choose to use as many processors as are needed and is charged accordingly.

The HP 9000 represents HP's newest line of computer servers. Its well-known line of HP 3000 computers has also been updated as the **HP e3000** and continue to support older applications as well as new ones.

HP e3000

The HP e3000 is a line of **midrange** business **servers** that carries on the well-known series of 3000 computers from **Hewlett-Packard** (HP). The e3000 uses HP's **MPE/iX operating system**, which can run applications written for the first 3000 systems that date as far back as the early 1970s and also run **POSIX**-conforming (**UNIX**-based) applications as well.

The HP e3000 servers are offered in a compact, entry-level ("a-class") model and several larger ("n-class") models. The "a-class" model is also suggested as a replacement for HP's older 3000 models, which will no longer be supported after April 30, 2002.

MPE/iX provides "Web connectivity" (support for **TCP/IP**) as well as the ability to develop and run applications written in **Java**.

HP OpenView

HP OpenView is a suite of business computer management or "**e-services**" programs from **Hewlett-Packard** (HP), which states that the suite is "among the world's 20 largest software businesses." The OpenView programs are frequently sold to **HP 9000** and **e3000** business server

customers. An HP customer's IT professionals can use OpenView to manage applications, device availability, network conditions and status, system performance, service and program maintenance, and storage resources. Altogether, there are about 30 different OpenView products.

HP9000

See "HP 9000"

HPSS

HPSS (High Performance Storage System) is a storage management system especially designed for moving large files and large amounts of data around a network that may consist of **parallel processing** computers, **supercomputers**, and clusters of high-end **workstations**. HPSS is especially valuable for moving around large amounts of data for scientific and other complex applications and for moving large video files across the network.

Geared to work with both directly-connected and **network-attached storage** devices, HPSS supports data transfer rates greater than 1 gigabytes per second and is aimed at enterprises that handle quantities of data in the **petabyte** range. The HPSS technology makes use of "data movers," which are specialized software modules geared to sending very large data streams.

A joint development of industry and the U.S. government, HPSS is the result of contributions from more than 20 organizations, including Transarc, Objectivity, IBM, Los Alamos National Laboratory, and the San Diego Supercomputer Center. HPSS vendors include Cray, SGI, Sun Microsystems, and Intel.

HP-UX

HP-UX is the UNIX-based **operating system** for the **HP 9000** series of business **servers** from **Hewlett-Packard**. The 9000 series spans a spectrum of business needs and server sizes, ranging from an "entry-level" server appropriate for an Internet **firewall**, **Web hosting**, or branch office use to a **midrange** server appropriate for advanced enterprise resource planning (**ERP**) or Web commerce, to a high-end model for larger-scale and more computing-intensive applications. HP's **SuperDome** computer is based on parallel operation of up to 64 9000 processors. All of these servers run HP-UX.

HP also offers the e3000 line of servers, evolved from its long-established HP3000. The e3000 servers use HP's **MPE/iX** operating system.

See "hue, saturation, and brightness"

HSCSD

See "High-Speed Circuit-Switched Data"

HSM

HSM (Hierarchical Storage Management) is **policy**-based management of file **backup** and **archiving** in a way that uses storage devices economically and without the user needing to be aware of when files are being retrieved from backup storage media. Although HSM can be implemented on a standalone system, it is more frequently used in the distributed network of an enterprise. The hierarchy represents different types of storage media, such as **redundant array of independent disks** systems, optical storage, or tape, each type representing a different level of cost and speed of retrieval when access is needed. For example, as a file ages in an archive, it can be automatically moved to a slower but less expensive form of storage. Using an HSM product, an administrator can establish and state guidelines for how often different kinds of files are to be copied to a backup storage device. Once the guideline has been set up, the HSM software manages everything automatically.

HSM adds to archiving and file protection for disaster recovery the capability to manage storage devices efficiently, especially in large-scale user environments where storage costs can mount rapidly. It also enables the automation of backup, archiving, and migration to the hierarchy of storage devices in a way that frees users from having to be aware of the storage policies. Older files can automatically be moved to less expensive storage. If needed, they appear to be immediately accessible and can be restored transparently from the backup storage medium. The apparently available files are known as *stubs* and point to the real location of the file in backup storage. The process of moving files from one storage medium to another is known as *migration*.

An administrator can set high and low thresholds for hard disk capacity that HSM software will use to decide when to migrate older or less-frequently used files to another medium. Certain file types, such as **executable** files (programs), can be excluded from those to be migrated.

HSRP

HT

See "handie talkie"

htaccess

.htaccess is the default name for a file that is used to indicate who can or cannot access the contents of a specific file directory from the Internet or an intranet. The .htaccess file is a configuration file that resides in a directory and indicates which users or groups of users can be allowed access to the files contained in that directory.

.htaccess was introduced as a directory-level, user authentication method along with the original programs developed for retrieving Web pages over the Internet, such as **Hypertext Transfer Protocol daemon**. When users type in a **Uniform Resource Locator** (the name of a Web site they want to go to), the URL begins with "http://". This command is recognized by the underlying Web server software program, HTTPd (for HyperText Transfer Protocol daemon). (A **daemon** is a program that sits waiting for requests for other programs.)

The main access control file used by HTTPd is the global access configuration file, which often resides at the **root directory** of the HTTPd server. .htaccess files are additional, directory-level access control files used by HTTPd.

When the HTTPd server receives a user's request for a document, it looks in the document's own directory, as well as higher up in the chain of directories for these types of access control files. If it finds .htaccess, it will look there to see whether or not the user is allowed to access the file. Based on the information it finds, it may ask the user for his or her user name and password first, before sending the requested document.

.htaccess is the default file name used by HTTPd when no other name has been indicated in the HTTPd server's resource configuration file, `srm.conf`. Another file name can be specified in this file, under the `AccessFileName <file>` line, where `<file>` would normally indicate .htaccess or another name. (In Netscape servers, this file name is called `.nsconfig`, and uses a different syntax from .htaccess.)

Whether or Not to Use .htaccess

.htaccess is often used in settings where a group network administrator wants to control who views or changes the contents of the directories that relate to his or her groups or users. In these settings, it is not practical or advisable to give the administrator primary access to all of the HTTPd server's functions, and all of its other directories and configuration files. Having the local-level control provided by .htaccess files allows more flexibility for the administrator to create and change directory access controls, as needed.

Some disadvantages to using .htaccess files have been noted: If an organization has several hundred .htaccess files on several hundred directories, each granting or denying user access to their own contents, it is more difficult for the company's network administrators to prepare a global access or authentication strategy and keep up with changes. Also, .htaccess files can be overwritten very easily, causing

problems for users who once could access a directory's contents, but now cannot. Finally, .htaccess files are more likely to be opened or retrieved by unauthorized users.

htm

htm is sometimes used as a short form of the file name **suffix** for an **HTML** file. For example, the file for our definition of *computer* might be named "computer.htm" instead of "computer.html". The main advantage is that it's one character shorter. The disadvantage is that it's not quite as easy to recognize as an HTML file. Prior to wide-spread use of Windows 95 and later systems, there was another reason to prefer the three-character suffix rather than the four-character. Certain operating systems, such as Windows 3.1 and OS/2 used the original DOS **operating system** naming conventions, in which names were limited to eight characters and suffixes to three characters. So it was safer to create file names and suffixes that met this "8.3" limitation. (For example, if you created an HTML page coding hypertext links to your other pages based on a four-character suffix (".html") system and then moved that page to a Web **server** that only allowed a three-character suffix, your file name suffixes would all be shortened and your links would no longer work. And if you created links with the three-character suffix and moved it to a server that always required four-character suffixes for HTML files, you would be in trouble again.)

Today, the operating systems most people are likely to create HTML pages on and serve them from are all operating systems (such as Windows 95/98/NT, Mac OS, and UNIX-based systems) that support longer file names and suffixes. So if you were building a new Web site, you would most likely use the four-character html suffix for clarity (unless you preferred the brevity of the three-character suffix) because you could know that you could safely use either suffix—as long as the suffixes in your links and your file names matched.

However, if you have an existing Web site that started out using the three-character suffix, you may prefer to leave everything as it is. If you do move to a server that requires a four-character suffix for server consistency, you could do a search-and-replace at that time.

HTML

HTML (Hypertext Markup Language) is the set of **markup** symbols or codes inserted in a file intended for display on a World Wide Web **browser** page. The markup tells the Web browser how to display a Web page's words and images for the user. Each individual markup code is referred to as an element (but many people also refer to it as a **tag**). Some elements come in pairs that indicate when some display effect is to begin and when it is to end.

HTML is a formal Recommendation by the World Wide Web Consortium (W3C) and is generally adhered to by the major browsers, Microsoft's Internet Explorer and Netscape's Navigator, which also provide some additional non-standard codes. The current version of HTML is **HTML 4.0**. However, both Internet Explorer and Netscape implement some features differently and provide non-standard extensions. Web developers using the more advanced features of HTML 4 may have to design pages for both browsers and send out the appropriate version to a user. Significant features in HTML 4 are sometimes described in general as **dynamic HTML**. What is sometimes referred to as HTML 5 is an extensible form of HTML called Extensible Hypertext Markup Language (**XHTML**).

HTML 4.0

HTML 4.0 was the final version of the Hypertext Markup Language (**HTML**) before the Extensible Markup Language (**XHTML**) and remains the set of **markup** on which most large Web sites today are based. Like all HTML levels, HTML 4.0 was the official "recommendation" of the World Wide Web Consortium (W3C), the group that suggests industry standards for the Web.

Among new features introduced in HTML 4.0 were:

- The **cascading style sheet**, the ability to control Web page content at multiple levels
- The ability to create richer forms
- Support for **frames** (which is already supported by the major browsers)
- Enhancements for tables that make it possible to use captions to provide table content for Braille or speech users
- The capability to manage pages so that they can be distributed in different languages

In practice, the two leading browsers, Netscape and Internet Explorer, support HTML 4.0 somewhat differently or offer non-standard approaches. These require Web developers that use more advanced features to create pages for each browser and send the appropriate pages to the user.

HTML comment

You can include a comment in an HTML document. A comment will not be displayed and will help you remember why you coded something a particular way. A comment might look like this:

```
<!--The following table gives us precise control of figure placement.-->
```

Hint: Be sure to include two hyphens after the exclamation point and two hyphens before the greater-than sign. Not all browsers are picky about this, but some may be.

HTTP

See "Hypertext Transfer Protocol"

HTTP 1.1

HTTP (**Hypertext Transfer Protocol**), the World Wide Web application protocol that runs on top of the Internet's **TCP/IP** suite of protocols, now exists in a newer version, HTTP 1.1, that promises to bring Web pages a little faster to your browser and reduce some of the Web's enormous traffic. Developed by a committee of the Internet Engineering Task Force (**IETF**) that includes the Web's chief creator Tim Berners-Lee, HTTP 1.1 exists as a "proposal," but in fact, most major Web servers and browser clients are at some stage of supporting it.

Here's a summary of how HTTP 1.1 makes information flow faster:

- Instead of opening and closing a connection for each application request, HTTP 1.1 provides a *persistent connection* that allows multiple requests to be batched or *pipelined* to an output **buffer**. The underlying **Transmission Control Protocol** layer can put multiple requests (and responses to requests) into one **TCP segment** that gets forwarded to the **Internet Protocol** layer for packet transmission. Because the number of connection and disconnection requests for a sequence of "get a file" requests is reduced, fewer packets need to flow across the Internet. Since requests are pipelined, **TCP segments** are more efficient. The overall result is less Internet traffic and faster performance for the user.

Persistent connection is similar to Netscape's HTTP 1.0 extension called KeepAlive, but provides better handling of requests that go through **proxy servers**.

- When a browser supporting HTTP 1.1 indicates it can decompress HTML files, a server will compress them for transport across the Internet, providing a substantial aggregate savings in the amount of data that has to be transmitted. (Image files are already in a compressed format so this improvement applies only to HTML and other non-image data types.)

In addition to persistent connections and other performance improvements, HTTP 1.1 also provides the ability to have multiple **domain names** share the same Internet address (**IP address**). This will simplify processing for Web servers that host a number of Web sites in what is sometimes called **virtual hosting**.

HTTPD

See "Hypertext Transfer Protocol daemon"

HTTPS

HTTPS (Secure Hypertext Transfer Protocol) is a Web protocol developed by Netscape and built into its browser that encrypts and decrypts user page requests as well as the pages that are returned by the Web server. HTTPS is really just the use of Netscape's Secure Socket Layer (SSL) as a sublayer under its regular HTTP application layering. (HTTPS uses port 443 instead of HTTP port 80 in its interactions with the lower layer, TCP/IP.) SSL uses a 40-bit key size for the RC4 stream encryption algorithm, which is considered an adequate degree of encryption for commercial exchange.

Suppose you use a Netscape browser to visit a Web site to view their online catalog. When you're ready to order, you will be given a Web page order form with a Uniform Resource Locator (URL) that starts with https://. When you click "Send," to send the page back to the catalog retailer, your browser's HTTPS layer will encrypt it. The acknowledgement you receive from the server will also travel in encrypted form, arrive with an https:// URL, and be decrypted for you by your browser's HTTPS sublayer.

HTTPS and SSL support the use of X.509 digital certificates from the server so that, if necessary, a user can authenticate the sender. SSL is an open, nonproprietary protocol that Netscape has proposed as a standard to the World Wide Consortium (W3C). HTTPS is not to be confused with SHTTP, a security-enhanced version of HTTP developed and proposed as a standard by EIT.

hub

Also see **stackable hub**.

In general, a hub is the central part of a wheel where the spokes come together. The term is familiar to frequent fliers who travel through airport "hubs" to make connecting flights from one point to another. In data communications, a hub is a place of convergence where data arrives from one or more directions and is forwarded out in one or more other directions. A hub usually includes a **switch** of some kind. (And a product that is called a "switch" could usually be considered a hub as well.) The distinction seems to be that the hub is the place where data comes together and the switch is what determines how and where data is forwarded from the place where data comes together. Regarded in its switching aspects, a hub can also include a **router**.

1) In describing network topologies, a hub **topology** consists of a **backbone** (main circuit) to which a number of outgoing lines can be attached ("dropped"), each providing one or more connection **port** for **device** to attach to. For Internet users not connected to a local area network, this is the general topology used by your access provider. Other common network topologies are the **bus** network and the **ring** network. (Either of these could possibly feed into a hub network, using a **bridge**.)

2) As a network product, a hub may include a group of **modem** cards for dial-in users, a gateway card for connections to a local area network (for example, an **Ethernet** or a **token ring**), and a connection to a line (the main line in this example).

hue, saturation, and brightness

Hue, saturation, and brightness are aspects of color in the red, green, and blue (RGB) scheme. These terms are most often used in reference to the color of each **pixel** in a cathode ray tube (CRT) display. All possible colors can be specified according to hue, saturation, and brightness (also called *brilliance*), just as colors can be represented in terms of the R, G, and B components.

Most sources of visible light contain energy over a band of wavelengths. Hue is the **wavelength** within the visible-light spectrum at which the energy output from a source is greatest. This is shown as the peak of the curves in the accompanying graph of intensity versus wavelength. In this example, all three colors have the same hue, with a wavelength slightly longer than 500 nanometers, in the yellow-green portion of the spectrum.

Saturation is an expression for the relative bandwidth of the visible output from a light source. In the diagram, the saturation is represented by the steepness of the slopes of the curves. Here, the outside curve represents a color having low saturation, the middle curve represents a color having greater saturation, and the inside curve represents a color with fairly high saturation. As saturation increases, colors appear more "pure." As saturation decreases, colors appear more "washed-out."

Brightness is a relative expression of the intensity of the energy output of a visible light source. It can be expressed as a total energy value (different for each of the curves in the diagram), or as the amplitude at the wavelength where the intensity is greatest (identical for all three curves). In the RGB color model, the amplitudes of red, green, and blue for a particular color can each range from 0 to 100 percent of full brilliance. These levels are represented by the range of decimal numbers from 0 to 255, or hexadecimal numbers from 00 to FF.

human factors

In industry, human factors (also known as **ergonomics**) is the study of how humans behave physically and psychologically in relation to particular environments, products, or services. Many large manufacturing companies have a Human Factors department or hire a consulting firm to study how any major new product will be accepted by the users that it is designed for. A human factors specialist typically has an advanced academic degree in Psychology or has special training. The term *usability* is now sometimes used as an alternative to *human factors*, although human factors is really a larger area of study, including responses that are unrelated to usability, such as reactions and preferences in relation to visual and other sensory stimuli.

In a typical human factors or usability study, a group of hired or volunteer test subjects that represent future end users is given tasks to do with a working prototype or early version of a product. Typically, a test subject is observed while doing a task, asked to react verbally as any problems occur or as observations are made, and interviewed after each test. (Test subjects have to be assured that it is the product—and not their own skills or capabilities—that is being tested.) Usually, the test is videotaped for later study. In some cases, successive corrections to the product are made during the course of testing.

Human factors study can focus on general human behavior in relation to technology (such as studies of how people react to various type styles and sizes), on a generic type of product (such as **wearable computers**), on specific environment or product designs as a whole, or on some specific design aspects of a particular environment or product. Depending on objectives, the result of human factors study can include suggestions on how to redesign the object of study or a general guideline for designing such an object.

In addition to relatively formal human factors study, human factors can be said to be underway any time a designer thinks about the effects of the design on the end user, and, in fact, much corrective design work goes on without formal testing. A relatively new object of study is the design of a **Web site**, either as a general problem or in order to build a specific Web site that meets user needs.

human-computer interaction

See "HCI"

humanware

Humanware is **hardware** and **software** that emphasizes user capability and empowerment and the design of the user interface. The process of building humanware generally consists of these steps:

1. Define users (age, mindset, environmental context, previous product experience and expectations, and so forth) and what they really want to do
2. Identify tasks they will need to do or capabilities they will want
3. Specify usability objectives (if possible, these should be measurable, such as how long to do something or how many mouse clicks to get to a specified task point) for each task or capability
4. Build a prototype of the user interface (it can be a paper or simulated prototype if time is short)
5. Test and verify or correct the prototype
6. Provide the prototype and usability objectives to the program designers and coders
7. Test the code against the prototype and objectives and, if necessary, redesign or recode the software
8. Test the product with users or valid test subjects and revise as necessary
9. Get feedback from users and continually improve the product

Philips Research uses the term for both software and hardware that is specially designed to interact with users, including its speech synthesis and speech recognition microchips.

Hungarian notation

In programming, Hungarian notation is a set of conventions for naming data objects in which a programmer adds a meaningful prefix of one or several characters to the object's name to identify what type of object it is. The conventions suggest, among other things, that programmers choose prefixes that are suggestive of the type of object named and are easy to remember. Consistency in naming is very important.

In one programmer's version of Hungarian notation, a form might have the prefix "frm" and, if the form name is "Switchboard," the extended name would be "frmSwitchboard." This makes it clear that the reference is to a form called "Switchboard," and not to some other type of object with the same name, such as a label (which might be called "lblSwitchboard"). The conventions were developed to define naming procedures that would help programmers create prefixes that would be easy to remember and would

make objects easy to identify, both for themselves and for other programmers that might work with their code in the future.

Dr. Charles Simonyi developed the convention at Microsoft, where it is used in the Windows source code. Microsoft says it's known as Hungarian notation because the prefixes make the names seem to be non-English and also because Simonyi is from Hungary. Since Microsoft uses it extensively, many programmers outside Microsoft use it. Charles Petzold's use of Hungarian notation in his book, "Programming Windows," also has influenced many Windows programmers.

hybrid fiber coaxial network

A hybrid fiber coaxial (HFC) network is a telecommunication technology in which **optical fiber** cable and **coaxial cable** are used in different portions of a **network** to carry **broadband** content (such as video, **data**, and voice). Using HFC, a local **CATV** company installs fiber optic cable from the cable head-end (distribution center) to serving nodes located close to business and residential users and from these nodes uses coaxial cable to individual businesses and homes. An advantage of HFC is that some of the characteristics of fiber optic cable (high **bandwidth** and low noise and interference susceptibility) can be brought close to the user without having to replace the existing coaxial cable that is installed all the way to the home and business.

Both cable TV and telephone companies are using HFC in new and upgraded networks and, in some cases, sharing the same infrastructure to carry both video and voice conversations in the same system. Scientific Atlanta lists four reasons why cable TV and telephone companies are upgrading facilities to HFC:

- 1) The use of fiber optic cable for the **backbone** paths allows more data to be carried than coaxial cable alone.
- 2) The higher bandwidth supports reverse paths for interactive data flowing back from the user.
- 3) That portion of the infrastructure with fiber optic cable is more reliable than coaxial cable. Reliability is perceived as more important in an interactive environment.
- 4) Fiber optic cable is more efficient for interconnecting cable TV or phone companies that are consolidating with geographically adjacent companies.

hybrid online analytical processing

Hybrid online analytical processing (HOLAP) is a combination of relational OLAP (**ROLAP**) and multi-dimensional OLAP (usually referred to simply as **OLAP**). HOLAP was developed to combine the greater data capacity of ROLAP with the superior processing capability of OLAP.

HOLAP can use varying combinations of ROLAP and OLAP technology. Typically it stores data in both a **relational database** (RDB) and a **multidimensional database** (MDDB) and uses whichever one is best suited to the type of processing desired. The databases are used to store data in the most functional way. For data-heavy processing, the data is more efficiently stored in a RDB, while for speculative processing, the data is more effectively stored in an MDDB.

HOLAP users can choose to store the results of queries to the MDDB to save the effort of looking for the same data over and over which saves time. Although this technique—called "materializing cells"—improves performance, it takes a toll on storage. The user has to strike a balance between performance and storage demand to get the most out of HOLAP. Nevertheless, because it offers the best features of both OLAP and ROLAP, HOLAP is increasingly preferred.

Hydra

See "Terminal Server product"

hyper

- 1) As an adjective, *hyper* is slang for "keyed up" or "overwrought."
- 2) Hyper is also a prefix, from the Greek *hyper-*, meaning over, above, or excessive, used in such terms as *hyperbole* (exaggeration in describing something) and **hypertext** (text that extends to point to or include other text).
- 3) In science, also as a prefix, hyper- is something that exists in a space of four or more dimensions, such as a *hyperplane*.

HyperCard

HyperCard is an early (1986) Macintosh **application** that enables users to author **hypertext** pages, called cards, without any programming knowledge. A set of cards, called a stack, can be linked together to allow readers to navigate through the stack in a non-linear manner by clicking on buttons or objects associated with an action script.

Hyper-G

Hyper-G is a publishing system with **hypertext** features more advanced than those available with the **Hypertext Transfer Protocol** and today's Web **browser**. Hyper-G was inspired in part by the ideas of Ted Nelson, who coined the term "hypertext," and was developed in Graz, Austria, by a team of researchers at the Institute for Information Processing and Computer Supported New Media (**IICM**) and the Institute for HyperMedia Systems (**IHM**) of Joanneum Research. Assistance was provided by developers elsewhere.

Using Hyper-G:

- You can have bi-directional links between HTML pages (or other hypertext documents). That is, you can know for any page what other HTML pages (including those at other Web sites) link to the page. The latter kind of link is known as a **backlink**.
- You can create *link types* (for example, for a single link, you might have one type called "definition" and another link type called "picture").
- Links can be defined as separate objects or files, allowing them to be easily filtered or changed for an entire document or set of files.
- One link type can be an annotation that an editor or a reviewer can create or modify. Thus, a number of collaborating reviewers or writers can share each others comments, made visible by the links they create.
- Links can overlap each other. For example, "client-server" could contain a link for "client," for "server," and another for the term "client-server" as a whole.
- The structure of a document can be viewed graphically and even in 3-D.
- The author can control who can see a document, who can see a link, who can edit the document, and who can edit the links.

Hyper-G is available in a commercial version called HyperWave. HyperWave consists of a server and clients that run on Windows and UNIX platforms. A version for Macintosh is in preparation. The most advanced client is the UNIX version; it can be run on **Linux** systems. HyperWave is compatible with **HTML**.

Among other applications, HyperWave has ideal features for online peer or technical reviews and collaborative writing. Among the early users of Hyper-G or derivative versions were Oxford University Press and the European Space Agency.

hyperlink

On the Web or other hypertext systems, hyperlink is a synonym for both **link** and **hypertext link**. Possibly, the term originated because "link" was not felt to be specific enough. And it's shorter than "hypertext link."

hypermedia

Hypermedia, a term derived from **hypertext**, extends the notion of the hypertext **link** to include links among any set of multimedia objects, including sound, motion video, and virtual reality. It can also connote a higher level of user/network interactivity than the interactivity already implicit in hypertext.

hyperspace

Hyperspace is a term that describes the total number of individual locations and all of their interconnections in a **hypertext** environment. It also connotes a perceived sense of this potentially confusing totality. If you've ever started out somewhere on the World Wide Web and gradually lost the sense that you know where you are going or where you are, you are in the condition known as "lost in hyperspace." (Studies, however, show that the "lost in hyperspace" problem is relatively low on users' lists of "things to improve.")

Hyperspace can be considered the hypertextual or architectural aspect of **cyberspace**, a term that has even richer connotations.

hypertext

Hypertext is the organization of information units into connected associations that a user can choose to make. An instance of such an association is called a **link** or hypertext link. (And the highlighted word "link" in the previous sentence is an example of a hypertext link.)

Hypertext was the main concept that led to the invention of the World Wide Web, which is, after all, nothing more (or less) than an enormous amount of information content connected by an enormous number of hypertext links.

The term was first used by Ted Nelson in describing his **Xanadu** system.

Also see **hypermedia**.

Hypertext Transfer Protocol daemon

On the Web, each **server** has an **HTTPD** or **Hypertext Transfer Protocol daemon** that waits in attendance for requests to come in from the rest of the Web. A *daemon* is a program that is "an attendant power or spirit" (Webster's). It sits waiting for requests to come in and then forwards them to other processes as appropriate.

Hypertext Transfer Protocol

The Hypertext Transfer Protocol (**HTTP**) is the set of rules for exchanging files (text, graphic images, sound, video, and other multimedia files) on the **World Wide Web**. Relative to the **TCP/IP** suite of protocols (which are the basis for information exchange on the Internet), HTTP is an application **protocol**.

Essential concepts that are part of HTTP include (as its name implies) the idea that files can contain references to other files whose selection will elicit additional transfer requests. Any **Web server** machine contains, in addition to the **HTML** and other files it can serve, an **HTTP daemon**, a program that is designed to wait for HTTP requests and handle them when they arrive. Your **Web browser** is an **HTTP client**, sending requests to server machines. When the browser user

enters file requests by either “opening” a Web file (typing in a **Uniform Resource Locator**) or clicking on a **hypertext link**, the browser builds an HTTP request and sends it to the **Internet Protocol address** indicated by the URL. The HTTP daemon in the destination server machine receives the request and, after any necessary processing, the requested file is returned.

The latest version of HTTP is **HTTP 1.1**.

i.LINK

i.LINK is the Sony Corporation implementation of a standard, **IEEE 1394**, High Performance Serial Bus, for connecting devices to your personal computer. i.LINK provides a single plug-and-socket connection on which up to 63 devices can be attached with data transfer speeds up to 400 **Mbps** (megabits per second). The standard describes a **serial bus** or pathway between one or more peripheral devices and your computer's **microprocessor**. Many peripheral devices now come equipped to meet IEEE 1394. i.LINK, Apple's **FireWire**, and other IEEE 1394 implementations provide:

- A simple common plug-in serial connector on the back of your computer and on many different types of peripheral devices
- A thin serial cable rather than the thicker parallel cable you now use to your printer, for example
- A very high-speed rate of data transfer that will accommodate multimedia applications (100 and 200 megabits per second today; with much higher rates later)
- Hot-plug and **plug and play** capability without disrupting your computer
- The ability to chain devices together in a number of different ways without terminators or complicated set-up requirements

In time, IEEE 1394 implementations are expected to replace and consolidate today's serial and parallel interfaces, including **Centronics parallel**, **RS-232C**, and Small Computer System Interface (**SCSI**). The first products to be introduced with FireWire include **digital cameras**, digital video discs (**DVDs**), digital video tapes, digital camcorders, and music systems. Because IEEE 1394 is a **peer-to-peer** interface, one camcorder can dub to another without being plugged into a computer. With a computer equipped with the socket and bus capability, any device (for example, a video camera) can be plugged in while the computer is running.

Briefly How It Works

There are two levels of interface in IEEE 1394, one for the **backplane** bus within the computer and another for the point-to-point interface between device and computer on the serial cable. A simple bridge connects the two environments. The backplane bus supports 12.5, 25, or 50 megabits per second data transfer. The cable interface supports 100, 200, or 400 megabits per second. Each of these interfaces can handle any of the possible data rates and change from one to another as needed.

The serial bus functions as though devices were in slots within the computer sharing a common memory space. A 64-bit device address allows a great deal of flexibility in configuring devices in chains and trees from a single socket.

IEEE 1394 provides two types of data transfer: asynchronous and **isochronous**. Asynchronous is for traditional load-and-store applications where data transfer can be initiated and an application interrupted as a given length of data arrives in a **buffer**. Isochronous data transfer ensures that data flows at a pre-set rate so that an application can handle it in a timed way. For multimedia applications, this kind of data transfer reduces the need for buffering and helps ensure a continuous presentation for the viewer.

The 1394 standard requires that a device be within 4.5 meters of the bus socket. Up to 16 devices can be connected in a single chain, each with the 4.5 meter maximum (before signal attenuation begins to occur) so theoretically you could have a device as far away as 72 meters from the computer.

Another new approach to connecting devices, the Universal Serial Bus (**USB**), provides the same "hot plug" capability as the 1394 standard. It's a less expensive technology but data transfer is limited to 12 Mbps (million bits per second). Small Computer System Interface offers a high data transfer rate (up to 40 megabytes per second) but requires address preassignment and a device terminator on the last device in a chain. FireWire can work with the latest internal computer **bus** standard, Peripheral Component Interconnect (**PCI**), but higher data transfer rates may require special design considerations to minimize undesired buffering for transfer rate mismatches.

I18N

See "internationalization"

I2C bus

The I2C (Inter-IC) bus is a bi-directional two-wire **serial bus** that provides a communication link between integrated circuits (**ICs**). Phillips introduced the I2C bus 20 years ago for mass-produced items such as televisions, VCRs, and audio equipment. Today, I2C is the de-facto solution for embedded applications.

There are three data transfer speeds for the I2C bus: standard, fast-mode, and high-speed mode. Standard is 100 **Kbps**. Fast-mode is 400 Kbps, and high-speed mode supports speeds up to 3.4 **Mbps**. All are **backward compatible**. The I2C bus supports 7-bit and 10-bit **address** space devices and devices that operate under different voltages.

I²C

See “I²C bus”

IA-64

IA-64 is a **64-bit processor** architecture developed at Intel that is based on Explicitly Parallel Instruction Computing (EPIC) and designed as the foundation for Intel’s line of microprocessors through 2005. The **Itanium** is the first in Intel’s line of IA-64 processors.

IAB

The IAB (Internet Architecture Board) is the **Internet Society** overseer of the technical evolution of the Internet. The IAB supervises the Internet Engineering Task Force (**IETF**), which oversees the evolution of **TCP/IP**, and the Internet Research Task Force (**IRTF**), which works on network technology.

IANA

IANA (Internet Assigned Numbers Authority) is the organization under the Internet Architecture Board (**IAB**) of the **Internet Society** that, under a contract from the U.S. government, has overseen the allocation of **Internet Protocol** addresses to Internet service providers (**ISPs**). IANA also has had responsibility for the registry for any “unique parameters and protocol values” for Internet operation. These include **port numbers**, character sets, and **MIME** media access types.

Partly because the Internet is now a global network, the U.S. government has withdrawn its oversight of the Internet, previously contracted out to IANA, and lent its support to a newly-formed organization with global, non-government representation, the Internet Corporation for Assigned Names and Numbers (**ICANN**). ICANN has now assumed responsibility for the tasks formerly performed by IANA.

IAP

An IAP (Internet access provider) is a company that provides individuals and other ISP companies access to the Internet. An IAP is a type of Internet service provider (**ISP**). (The other main service that an ISP provides is **Web site building** and **virtual hosting**.) An IAP has the equipment and the telecommunication line access required to have **POP** on the Internet for the geographic area served. The larger IAPs have their own high-speed leased lines so that they are less dependent on the telecommunication providers and can provide better service to their customers. Among the largest national and regional ISPs are AT&T WorldNet, IBM Global Network, MCI, Netcom, UUNet, and PSINet.

IAPs also include regional providers such as New England’s NEARNet and the San Francisco Bay area BARNet. They also include thousands of local providers. In addition, Internet users can also get access through online service providers (**OSP**) such as America Online.

The larger IAPs interconnect with each other through **MAE** (ISP switching centers run by MCI WorldCom) or similar centers. The arrangements they make to exchange traffic are known as **peering** agreements. There are several very comprehensive lists of IAPs (usually identified as ISPs) available to Web users.

iButton

An iButton is a **microchip** similar to those used in a **smart card** but housed in a round stainless steel button of 17.35mm × 3.1mm—5.89mm in size (depending on the function). The iButton was invented and is still manufactured exclusively by Dallas Semiconductor mainly for applications in harsh and demanding environments.

Like a smart card, an iButton does not have an internal power source. It requires connection to a reader (known as a Blue Dot Receptor) in order to be supplied with power and to receive input and send output. Unlike some smart cards, there are currently no contactless iButtons: They require physical contact with a reader to function.

There are iButtons that measure temperature (for food storage and transport); have an electronic ID (for physical access to buildings); and store e-cash (for purchases both in stores and via the web). For **e-commerce** applications, the iButton can support JavaCard 2.0/OpenCard standards in addition to proprietary software.

iButtons have an advantage over conventional smart cards in term of durability and longevity. The stainless steel casing gives iButton a far greater ability to survive in a range of temperatures—all versions are functional from -40 C to +70 C—and in a much harsher range of environments (such as exposure to salt water and long term exposure to physical impacts) than the plastic smart card. For e-commerce and personal ID usage, iButtons can be mounted on a range of personal accessories: Watch, ring, key chain, or dog tag.

As of early 2000, Dallas Semiconductor had shipped over 27 million iButtons around the world. This figure is below that of smart cards because of a larger installed user base for smart cards, the comparatively high cost of iButtons, the fact that iButtons have a long life, and because Dallas Semiconductor has not licensed the patents for external manufacture. Thus far, the major successes for iButton have been in Turkey as an e-purse for the mass transit system; in Argentina and Brazil for parking meters; and in the U.S. as Blue Mailbox attachments that improve postal efficiency.

IC

See "integrated circuit"

ICANN

ICANN (Internet Corporation for Assigned Names and Numbers) is the private (non-government) non-profit corporation with responsibility for **IP address** space allocation, **protocol** parameter assignment, **domain name system** management, and **root server system** management functions, the services previously performed by the Internet Assigned Numbers Authority (**IANA**). (ICANN is usually pronounced EYE-can, as in "I can at least try to manage the Internet.")

Initial members of the ICANN board were chosen by the late Dr. Jonathon Postel, who headed IANA. IANA derived its authority under a contract from the U.S. government which financed the original research network, **Advanced Research Projects Agency Network**, from which the Internet grew. The need to internationalize the governing of the Internet (among other concerns) led the U.S. government to recommend the origin of ICANN as a global, government-independent entity to manage the systems and protocols that keep the Internet going. The U.S. government is essentially turning over control of the Internet to ICANN although domain name registration performed by Network Solutions, Inc. will continue to be under U.S. government contract for a limited time.

ICANN has a board of nineteen Directors, nine At-Large Directors, nine to be nominated by Supporting Organizations, and the President/CEO (ex officio). The nine At-Large Directors of the Initial Board are serving one-year terms and will be succeeded by At-Large Directors elected by an at-large membership organization.

Since its beginning, ICANN has had to deal with controversial issues (such as what new top-level domain names should be permitted and whether alternative root server systems should be allowed).

ice

For ICE, see **Information and Content Exchange**.

Ice, jello, and liquid are related terms describing three approaches to controlling content placement on a Web page. Because the **browser** user can control and change both screen resolution and window size, the Web page designer is challenged to design a page that will achieve its intended effect in spite of user resizing.

An ice page is one in which the primary content has a fixed width in **pixels** and assumes a left margin alignment. Such a page is designed to display optimally on one particular display resolution setting and window size and either specifies or assumes that size. If the resolution is set to a

different setting, the page may have unneeded space on the right size of the display window, but this is a risk that the designer chooses to take.

A jello page is one in which the primary content is centered on the page. It also has a fixed-width column, but it is always centered in any size window and at any display resolution. Its center alignment eliminates the excessive right margin seen in an "ice" page (when viewed on a large monitor). But it can have excessive margins on both sides of the centered content.

A liquid page, according to Glenn Davis of Project Cool, is (to paraphrase slightly): "...a Web page that will reflow to fit no matter what size window you pour it into." Unlike the ice and jello approaches, a liquid page or content area leaves no blank margin on the right or the left. However, unless special care is taken, elements in a liquid page can sometimes have too much or too little space between them.

More sophisticated designers sometimes use a combination of tables and tables-within-tables to define and control layout space and element placement in the various resolutions and windows sizes users may choose to use. To create liquid content spaces or pages, you may be able to determine the window size and dynamically adjust your content layout to meet each user's requirements.

ICM file

In Windows 95 and possibly other operating systems, an ICM (Image Color Matching) file contains a color system profile for a particular application or device such as a color printer or scanner. This profile is matched to a common profile that in turn can be mapped to other device's individual profiles. This allows the color system used by one computer device to match the colors used by other applications and devices on the same or other computer platforms. A profile commonly adopted by some programs and devices is the Kodak Professional Color System profile. An ICM file usually carries the suffix ".icm".

Microsoft, Apple, and Adobe are among the manufacturers who adhere to the ICC's color profiling system.

ICMP

ICMP (Internet Control Message Protocol) is a message control and error-reporting protocol between a **host** server and a **gateway** to the Internet. ICMP uses Internet Protocol (**IP**) **datagrams**, but the messages are processed by the IP software and are not directly apparent to the application user.

icon

1) In a computer's graphical user interface (**GUI**), an icon (pronounced EYE-kahn) is an image that represents an application, a capability, or some other concept or specific

entity with meaning for the user. An icon is usually selectable but can also be a nonselectable image such as a company's logo.

2) On a Web page, an icon is often a graphical image that represents the topic or information category of another Web page. Frequently, the icon is a hypertext **link** to that page. Typically, icons are gathered in one or two places on a page, either as separate graphic files or as a single **image map**.

3) Icon is also a lexical programming language, commonly thought to be an evolution of the SNOBOL programming language.

ICP

An ICP (Internet commerce provider) is a company that sells software and services that enable a merchant with a **Web site** to build an online store on the merchant's own site or on the provider's site. Products and services can be pre-packaged or customized or some combination. Typically, a pre-packaged ICP product lets a merchant set up an online store using one of several design templates, arranges for secure credit card transactions, and provides order tracking. An ICP may also provide services related to order fulfillment, such as shipping and customer relations.

Some Internet access providers (**IAP**) and Web design shops also act as ICPs, offering customized services or serving as a vendor of packaged products.

ICQ

ICQ ("I Seek You") is a program you can download that will let you know when friends and contacts are also online on the Internet. ICQ allows you to page them, chat with them, and initiate and participate in PC-to-PC calls, PC-to-phone and phone-to-phone calling cards calls. Like AOL's Instant Messenger (**AIM**), in order to use ICQ, both parties must have downloaded the program.

ICQ enables you to send messages, files (single, multiple or whole directories), and URLs directly to your friends. In addition, you can initiate an IRC-style chat session or voice and video-voice connection and play games with other ICQ members that you are in touch with. Your contact is signaled of an incoming event in real time and has immediate access to it.

IDE

IDE (Integrated Drive Electronics) is a standard electronic **interface** used between a computer **motherboard's** data paths or **bus** and the computer's disk storage devices. The IDE interface is based on the IBM PC Industry Standard Architecture (**ISA**) 16-bit **bus** standard, but it is also used in computers that use other bus standards. Most computers sold today use an enhanced version of IDE called Enhanced

Integrated Drive Electronics (**EIDE**). IDE gets its name because the disk drive controller is built into the logic board in the disk drive.

IDE was adopted as a standard by American National Standards Institute (**ANSI**) in November 1990. The ANSI name for IDE is Advanced Technology Attachment (**ATA**). The IDE (ATA) standard is one of several related standards maintained by the T10 Committee.

IDEA

See "International Data Encryption Algorithm"

IDEN

iDEN (Integrated Digital Enhanced Network) is a **wireless** technology from Motorola combining the capabilities of a digital **cellular telephone**, two-way radio, alphanumeric **pager**, and data/fax **modem** in a single network. iDEN operates in the 800 **MHz**, 900MHz, and 1.5 **GHz** bands and is based on time division multiple access (**TDMA**) and **GSM** architecture. It uses Motorola's Vector Sum Excited Linear Predictors (**VSELP**) **vocoder** for voice compression and **QAM** modulation to deliver 64 **Kbps** over a 25 KHz channel.

iDEN is designed to give the mobile user quick access to information without having to carry around several devices. In early 2001, a new iDEN handset is scheduled for release that will tackle added business needs like logistics management and alerts.

Currently, iDEN systems work in more than a dozen countries.

IDF

See "interface device"

IDL

1) IDL (interface definition language) is a generic term for a language that lets a program or **object** written in one language communicate with another program written in an unknown language. In distributed object technology, it's important that new objects be able to be sent to any platform environment and discover how to run in that environment. An Object Request Broker (**ORB**) is an example of a program that would use an interface definition language to "broker" communication between one object program and another one.

An interface definition language works by requiring that a program's interfaces be described in a **stub** or slight extension of the program that is compiled into it. The stubs in each program are used by a broker program to allow them to communicate.

2) IDL (Interactive Data Language) is a language for creating visualizations based on scientific or other data.

3) IDL (interactive distance learning) is a general term for learning that takes place through remote telecommunication and that allows students to participate from a distance. Television has been used for many years for non-interactive distance learning. Teleconference classes are becoming more common where higher bandwidth and such technologies as ISDN and satellite communication permit. The World Wide Web, with or without multimedia, offers new possibilities.

idoru

An idoru is a virtual (computer-created) media star. If real pop music stars sometimes seem to become the conception of their producers' dreams, perhaps it would be simpler to start from scratch and design your own media star to perform (think of a fully-developed **hologram** singing and dancing before tens of thousands of insane fans in Central Park), be interviewed by *Rolling Stone*, and even evolve and grow older! The idea is explored in the novel, *Idoru*, by science-fiction writer William Gibson.

IDSL

IDSL is a system in which digital data is transmitted at 128 **Kbps** on a regular copper telephone line (**twisted pair**) from a user to a destination using digital (rather than analog or voice) transmission, bypassing the telephone company's central office equipment that handles analog signals. IDSL uses the Integrated Services Digital Network (**ISDN**) **Basic Rate Interface in ISDN** transmission code.

IDSL is a technology developed by Ascend Communications (now part of Lucent Technologies). IDSL is an expedient approach that allows use of existing ISDN card technology for data-only use.

The differences between IDSL and ISDN are:

- ISDN passes through the phone company's central office voice network; IDSL bypasses it by plugging into a special router at the phone company end
- ISDN requires call setup; IDSL is a dedicated service
- ISDN may involve per-call fees; IDSL may be billed at a flat rate with no usage charges

IEC

See "International Electrotechnical Commission"

IEEE

The IEEE (Institute of Electrical and Electronics Engineers) describes itself as "the world's largest technical professional society—promoting the development and application of electrotechnology and allied sciences for the benefit of humanity, the advancement of the profession, and the well-being of our members."

The IEEE fosters the development of standards that often become national and international standards. The organization publishes a number of journals, has many local chapters, and several large societies in special areas, such as the IEEE Computer Society.

IEEE 1394

IEEE 1394, High Performance Serial Bus, is an electronics standard for connecting devices to your personal computer. IEEE 1394 provides a single plug-and-socket connection on which up to 63 devices can be attached with data transfer speeds up to 400 **Mbps** (**megabits** per second). The standard describes a **serial bus** or pathway between one or more peripheral devices and your computer's **microprocessor**. Many peripheral devices now come equipped to meet IEEE 1394. Two popular implementations of IEEE 1394 are Apple's **FireWire** and Sony's **i.LINK**. IEEE 1394 implementations provide:

- A simple common plug-in serial connector on the back of your computer and on many different types of peripheral devices
- A thin serial cable rather than the thicker parallel cable you now use to your printer, for example
- A very high-speed rate of data transfer that will accommodate multimedia applications (100 and 200 megabits per second today; with much higher rates later)
- Hot-plug and **plug and play** capability without disrupting your computer
- The ability to chain devices together in a number of different ways without terminators or complicated set-up requirements

In time, IEEE 1394 implementations are expected to replace and consolidate today's serial and parallel interfaces, including **Centronics parallel**, **RS-232C**, and Small Computer System Interface (**SCSI**). The first products to be introduced with FireWire include **digital cameras**, digital video discs (**DVDs**), digital video tapes, digital camcorders, and music systems. Because IEEE 1394 is a **peer-to-peer** interface, one camcorder can dub to another without being plugged into a computer. With a computer equipped with the socket and bus capability, any device (for example, a video camera) can be plugged in while the computer is running.

Briefly How It Works

There are two levels of interface in IEEE 1394, one for the **backplane** bus within the computer and another for the point-to-point interface between device and computer on the serial cable. A simple bridge connects the two environments. The backplane bus supports 12.5, 25, or 50 megabits per second data transfer. The cable interface supports 100, 200, or 400 megabits per second. Each of these interfaces can handle any of the possible data rates and change from one to another as needed.

The serial bus functions as though devices were in slots within the computer sharing a common memory space. A 64-bit device address allows a great deal of flexibility in configuring devices in chains and trees from a single socket.

IEEE 1394 provides two types of data transfer: asynchronous and **isochronous**. Asynchronous is for traditional load-and-store applications where data transfer can be initiated and an application interrupted as a given length of data arrives in a **buffer**. Isochronous data transfer ensures that data flows at a pre-set rate so that an application can handle it in a timed way. For multimedia applications, this kind of data transfer reduces the need for buffering and helps ensure a continuous presentation for the viewer.

The 1394 standard requires that a device be within 4.5 meters of the bus socket. Up to 16 devices can be connected in a single chain, each with the 4.5 meter maximum (before signal attenuation begins to occur) so theoretically you could have a device as far away as 72 meters from the computer.

Another new approach to connecting devices, the Universal Serial Bus (**USB**), provides the same “hot plug” capability as the 1394 standard. It’s a less expensive technology but data transfer is limited to 12 Mbps (million bits per second). Small Computer System Interface offers a high data transfer rate (up to 40 megabytes per second) but requires address preassignment and a device terminator on the last device in a chain. FireWire can work with the latest internal computer **bus** standard, Peripheral Component Interconnect (**PCI**), but higher data transfer rates may require special design considerations to minimize undesired buffering for transfer rate mismatches.

IETF

The IETF (Internet Engineering Task Force) is the body that defines standard Internet operating **protocols** such as **TCP/IP**. The IETF is supervised by the **Internet Society’s** Internet Architecture Board (**IAB**). IETF members are drawn from the Internet Society’s individual and organization membership. Standards are expressed in the form of Requests for Comments (**RFCs**).

IGMP

See “Internet Group Management Protocol”

IGP

An IGP (Interior Gateway Protocol) is a protocol for exchanging routing information between **gateways** (**hosts** with **routers**) within an autonomous network (for example, a system of corporate local area networks). The routing information can then be used by the Internet Protocol (**IP**) or other network protocols to specify how to route transmissions.

There are two commonly used IGPs: the **Routing Information Protocol** (**RIP**) and the Open Shortest Path First (**OSPF**) protocol.

Also see the Exterior Gateway Protocol (**EGP**).

IIOP

IIOP (Internet Inter-ORB Protocol) is a **protocol** that makes it possible for **distributed** programs written in different programming languages to communicate over the Internet. IIOP is a critical part of a strategic industry standard, the Common Object Request Broker Architecture (**CORBA**). Using CORBA’s IIOP and related protocols, a company can write programs that will be able to communicate with their own or other company’s existing or future programs wherever they are located and without having to understand anything about the program other than its service and a name. CORBA and IIOP compete with a similar strategy from Microsoft called the Distributed Component Object Model (**DCOM**). (Microsoft and the Object Management Group, sponsors of CORBA, have agreed to develop software bridges between the two models so that programs designed for CORBA can communicate with programs designed for DCOM.)

CORBA and IIOP assume the **client/server** model of computing in which a client program always makes requests and a server program waits to receive requests from clients. When writing a program, you use an interface called the General Inter-ORB Protocol (**GIOP**). The GIOP is implemented in specialized mappings for one or more network transport layers. Undoubtedly, the most important specialized mapping of GIOP is IIOP, which passes requests or receives replies through the Internet’s transport layer using the Transmission Control Protocol (**TCP**). Other possible transport layers would include IBM’s Systems Network Architecture (**SNA**) and Novell’s **IPX**.

For a client to make a request of a program somewhere in a network, it must have an address for the program. This address is known as the Interoperable Object Reference (**IOR**). Using IIOP, part of the address is based on the server’s port number and **IP address**. In the client’s computer, a table can be created to map IORs to proxy names that are easier to use. The GIOP lets the program make a connection with an IOR and then send requests to it (and lets servers send replies). A Common Data Representation (**CDR**) provides a way to encode and decode data so that it can be exchanged in a standard way.

A somewhat similar protocol, the Remote Method Invocation (**RMI**), was developed by Sun Microsystems to serve its cross-platform framework for the **Java** programming language. Sun has provided a way so that programming that uses the RMI can be mapped to IIOP.

IIS

IIS (Internet Information Server) is a group of Internet servers (including a Web or **Hypertext Transfer Protocol** server and a **File Transfer Protocol** server) with additional capabilities for Microsoft's **Windows NT** and **Windows 2000** Server operating systems. IIS is Microsoft's entry to compete in the Internet server market that is also addressed by **Apache**, Sun Microsystems, O'Reilly, and others. With IIS, Microsoft includes a set of programs for building and administering Web sites, a search engine, and support for writing Web-based applications that access **databases**. Microsoft points out that IIS is tightly integrated with the Windows NT and 2000 Servers in a number of ways, resulting in faster Web page serving.

A typical company that buys IIS can create pages for Web sites using Microsoft's Front Page product (with its **WYSIWYG** user interface). Web developers can use Microsoft's **Active Server Page** (ASP) technology, which means that applications—including **ActiveX controls**—can be imbedded in Web pages that modify the content sent back to users. Developers can also write programs that filter requests and get the correct Web pages for different users by using Microsoft's Internet Server Application Program Interface (**ISAPI**) interface. ASPs and ISAPI programs run more efficiently than common gateway interface (**CGI**) and server-side include (**SSI**) programs, two current technologies. (However, there are comparable interfaces on other platforms.)

Microsoft includes special capabilities for server administrators designed to appeal to Internet service providers (**ISPs**). It includes a single window (or "console") from which all services and users can be administered. It's designed to be easy to add components as **snap-ins** that you didn't initially install. The administrative windows can be customized for access by individual customers.

IIS works closely with the **Microsoft Transaction Server** to access databases and provide control at the transaction level. It also works with Microsoft's Netshow in the delivery of streaming audio and video, delayed or live.

ILEC

An ILEC (incumbent local exchange carrier) is a telephone company in the U.S. that was providing local service when the **Telecommunications Act of 1996** was enacted. ILECs include the former Bell operating companies (**BOCs**) which were grouped into holding companies known collectively as the regional Bell operating companies (**RBOCs**) when the Bell System was broken up by a 1983 consent decree. ILECs are in contradistinction to **CLECs** (competitive local exchange carriers).

A "local exchange" is the local "central office" of an LEC. Lines from homes and businesses terminate at a local exchange. Local exchanges connect to other local exchanges

within a local access and transport area (**LATA**) or to interexchange carriers (**IXCs**) such as long-distance carriers AT&T, MCI, and Sprint.

iLINK

See "i.LINK"

illegal operation

An illegal operation, a term often seen in error messages, is a command to the **operating system** or an instruction to the computer **processor** that specifies an operation that is unknown to the operating system or processor and that therefore can't be performed. The result is that the operating system or processor usually terminates the program that made the "illegal" request. If that program was an application that you were using, you may find that data you were entering was lost or, in some cases, can be recovered from a backed-up copy that the system made for you.

A computer's processor knows what operation to perform as the result of an operation code (or *opcode*) within the instruction. Failing to recognize an opcode, the processor will return information to the operating system which in turn will usually terminate the application program that sent the bad instruction and issue a message to the user about the illegal operation. An illegal operation may mean a **bug** in the application program (or occasionally in the operating system) or it may be the result of a combination of unusual circumstances that the program and operating system could or did not anticipate. In the latter case, the problem may not be repeated or may be intermittent.

The usual practice if you get an illegal operation message is to continue working if the application is still running, or to restart the program if it has been terminated, and, if the problem recurs, to reboot the operating system and try again. If you continue to experience illegal operation errors with an application, report the problem to the software vendor.

ILOVEYOU virus

The ILOVEYOU virus comes in an e-mail note with "I LOVE YOU" in the subject line and contains an attachment that, when opened, results in the message being re-sent to everyone in the recipient's Microsoft Outlook address book and, perhaps more seriously, the loss of every **JPEG**, **MP3**, and certain other files on the recipient's hard disk. Because Microsoft Outlook is widely installed as the e-mail handler in corporate networks, the ILOVEYOU virus can spread rapidly from user to user within a corporation. On May 4, 2000, the virus spread so quickly that e-mail had to be shut down in a number of major enterprises such as the Ford Motor Company. The virus reached an estimated 45 million users in a single day.

The attachment in the ILOVEYOU virus is a **VBScript** program that, when opened (for example, by double-clicking on it with your mouse), finds the recipient's Outlook address book and re-sends the note to everyone in it. It then overwrites (and thus destroys) all files of the following file types: JPEG, MP3, VPOS, JS, JSE, CSS, WSH, SCT and HTA. Users who don't have a backup copy will have lost these files. (In March 1999, a virus named **Melissa virus** also replicated itself by using Outlook address books, but was less harmful in destroying user files.) The ILOVEYOU virus also resets the recipient's Internet Explorer start page in a way that may cause further trouble, resets certain Windows **registry** settings, and also acts to spread itself through Internet Relay Chat (**Internet Relay Chat**).

One of the first steps companies used to ward off the ILOVEYOU virus was to screen out notes with ILOVEYOU in the subject line. However, hackers quickly introduced copycat variations with subject lines variously identifying "JOKE" and "Mother's Day!" as the content, but containing the same or similar VBScript code. At least 12 variations have been identified. The most sinister mutation is undoubtedly the one with the subject line containing "VIRUS ALERT!!!" Posing as a virus fix from Symantec, the note starts out with "Dear Symantec Customer." The attachment (which should not be opened) is "protect.vbs."

Companies and users are advised to get or update **anti-virus software** that can help screen for the virus and remove it for users whose systems have been infected. Users are always advised never to open an e-mail attachment without screening it with anti-virus software or knowing exactly who sent it and what it is.

IM

See "instant messaging"

iMac

Now offered in multiple designer colors, the iMac is a low-cost version of Apple Computer's **Macintosh**. The iMac was designed to attract people who have never owned a personal computer and also to win back former Mac users who have moved to **personal computers**. Released in mid-August 1998, the initial version of the iMac featured a sleekly-molded designer-colored translucent case with a built-in 15-inch display, a fast 233 **MHz** processor, and the Mac OS **operating system**. Traditionally, somewhat higher in price than Intel-based PCs, a low-priced Mac symbolized Apple's determination to compete in and increase its share of the personal computer market. The iMac's designers have omitted a floppy disk drive with the idea that few users will miss it. Apple is advertising the iMac as easy to set up and ideal for simple applications and surfing the Web (the "i" in its name is said to stand for "Internet").

image

Also see **imaging**.

An image is a visual representation of something. In information technology, the term has several usages:

- 1) An image is a picture that has been created or copied and stored in electronic form. An image can be described in terms of **vector graphics** or **raster graphics**. An image stored in raster form is sometimes called a **bitmap**. An **image map** is a file containing information that associates different locations on a specified image with **hypertext** links.
- 2) An image is a section of random access memory (**RAM**) that has been copied to another memory or storage location.

image compression

Image compression is minimizing the size in bytes of a graphics file without degrading the quality of the image to an unacceptable level. The reduction in file size allows more images to be stored in a given amount of disk or memory space. It also reduces the time required for images to be sent over the Internet or downloaded from Web pages.

There are several different ways in which image files can be compressed. For Internet use, the two most common compressed graphic image formats are the **JPEG** format and the **GIF** format. The JPEG method is more often used for photographs, while the GIF method is commonly used for line art and other images in which geometric shapes are relatively simple.

Other techniques for image compression include the use of **fractals** and **wavelets**. These methods have not gained widespread acceptance for use on the Internet as of this writing. However, both methods offer promise because they offer higher compression ratios than the JPEG or GIF methods for some types of images. Another new method that may in time replace the GIF format is the **PNG** format.

A text file or program can be compressed without the introduction of errors, but only up to a certain extent. This is called *lossless compression*. Beyond this point, errors are introduced. In text and program files, it is crucial that compression be lossless because a single error can seriously damage the meaning of a text file, or cause a program not to run. In image compression, a small loss in quality is usually not noticeable. There is no "critical point" up to which compression works perfectly, but beyond which it becomes impossible. When there is some tolerance for loss, the compression factor can be greater than it can when there is no loss tolerance. For this reason, graphic images can be compressed more than text files or programs.

image map

In Web page development, an image map is a graphic image defined so that a user can click on different areas of the image and be linked to different destinations. You make an

image map by defining each of the sensitive areas in terms of their **x and y coordinates** (that is, a certain horizontal distance and a certain vertical distance from the left-hand corner of the image). With each set of coordinates, you specify a **Uniform Resource Locator** or Web address that will be linked to when the user clicks on that area.

The X and Y coordinates are expressed in **pixels** either in a separate file called a map file or in the same HTML file that contains the link to the image map. Popular tools like MapEdit provide a graphical interface for creating an image map (so that you don't have to figure out the X and Y coordinate numbers yourself).

Originally, the map file had to be sent to the server. Now the creator can place the map information either at the server or at the client (a "client-side map").

Image maps are used widely on many Web sites as a more adventuresome form of main menu.

imaginary number

An imaginary number is a quantity of the form ix , where x is a **real number** and i is the positive square root of -1 . The term "imaginary" probably originated from the fact that there is no real number z that satisfies the equation $z^2 = 1$. But imaginary numbers are no less "real" than real numbers. The quantity i is called the *unit imaginary number*. In engineering, it is denoted j , and is known as the *j operator*.

The unit imaginary number has some intriguing properties. For example:

$$(-i)^2 = -1$$

but $-i$ is different from i

$$i^3 = i^2i = (-1)i = -i$$

$$i^4 = i^2i^2 = (-1)(-1) = 1$$

$$i^5 = i^3i^2 = (i^3)(-1) = (-i)(-1) = i$$

$$i^n = i^{(n-4)}$$

when n is a **natural number** larger than 4

As i is raised to higher natural-number powers, the resultant cycles through four values: i , -1 , $-i$, and 1 in that order. No real number behaves like that!

The set **I** of imaginary numbers consists of the set of all possible products iw , where w is an element of the set **R** of real numbers. Therefore, the sets **I** and **R** are in one-to-one correspondence. The sum $v + iw$ of a real number v and an imaginary number iw forms a **complex number**. The set **C** of all complex numbers corresponds one-to-one with the set R^2 of all ordered pairs of real numbers. The set **C** also corresponds one-to-one with the points on a geometric plane.

Imaginary and complex numbers are used in engineering, particularly in electronics. Real numbers denote electrical **resistance**, imaginary numbers denote **reactance**, and complex numbers denote **impedance**.

imaging

Imaging is the capture, storage, manipulation, and display of **images**. In document imaging, the emphasis is on capturing, storing, and retrieving information from the images (which are often mainly images of text). In graphical imaging, the emphasis is on the manipulation of created images in order to achieve special effects through rotating, stretching, blurring, resizing, twirling, and other changes to the original image.

IMAP

See "Internet Message Access Protocol"

IMHO

Like FYI (for your information), IMHO (in my humble opinion) is an abbreviation for a phrase sometimes used in online chatting and e-mail. Variations include IMNSHO (in my not so humble opinion).

For similar terms, see **chat abbreviations**.

IMing

See "instant messaging"

i-Mode

i-Mode is the **packet-based** service for mobile phones offered by Japan's leader in wireless technology, NTT DoCoMo. Unlike most of the key players in the wireless arena, i-Mode eschews the Wireless Application Protocol (WAP) and uses a simplified version of HTML, Compact Wireless Markup Language (CWML) instead of WAP's Wireless Markup Language (WML). NTT DoCoMo has said that eventually it will support WAP and WML, but the company has not said exactly when this will happen.

First introduced in 1999, i-Mode was the world's first smart phone for Web browsing. The i-Mode wireless data service offers color and video over many phones. Its mobile computing service enables users to do telephone banking, make airline reservations, conduct stock transactions, send and receive e-mail, and have access to the Internet. As of early 2000, i-Mode had an estimated 5.6 million users.

impedance

Impedance, denoted Z , is an expression of the opposition that an electronic component, circuit, or system offers to alternating and/or direct electric **current**. Impedance is a vector (two-dimensional) quantity consisting of two independent scalar (one-dimensional) phenomena: **resistance** and **reactance**.

Resistance, denoted R , is a measure of the extent to which a substance opposes the movement of electrons among its atoms. The more easily the atoms give up and/or accept

electrons, the lower the resistance, which is expressed in positive **real number** ohms. Resistance is observed with alternating current (AC) and also with direct current (DC). Examples of materials with low resistance, known as electrical conductors, include copper, silver, and gold. High-resistance substances are called insulators or dielectrics, and include materials such as polyethylene, mica, and glass. A material with an intermediate levels of resistance is classified as a **semiconductor**. Examples are **silicon**, germanium, and **gallium arsenide**.

Reactance, denoted X , is an expression of the extent to which an electronic component, circuit, or system stores and releases energy as the current and voltage fluctuate with each AC cycle. Reactance is expressed in **imaginary number** ohms. It is observed for AC, but not for DC. When AC passes through a component that contains reactance, energy might be stored and released in the form of a magnetic field, in which case the reactance is inductive (denoted $+jX_L$); or energy might be stored and released in the form of an electric field, in which case the reactance is capacitive (denoted $-jX_C$). Reactance is conventionally multiplied by the positive square root of -1 , which is the unit imaginary number called the j operator, to express Z as a **complex number** of the form $R + jX_L$ (when the net reactance is inductive) or $R - jX_C$ (when the net reactance is capacitive).

The illustration shows a coordinate plane modified to denote complex-number impedances. Resistance appears on the horizontal axis, moving toward the right. (The left-hand half of this coordinate plane is not normally used because negative resistances are not encountered in common practice.) Inductive reactance appears on the positive imaginary axis, moving upward. Capacitive reactance is

depicted on the negative imaginary axis, moving downward. As an example, a complex impedance consisting of 4 ohms of resistance and $+j5$ ohms of inductive reactance is denoted as a vector from the origin to the point on the plane corresponding to $4 + j5$.

In series circuits, resistances and reactances add together independently. Suppose a resistance of 100.00 ohms is connected in a series circuit with an inductance of 10.000 μH . At 4.0000 MHz, the complex impedance is:

$$Z_{RL} = R + jX_L = 100.00 + j251.33$$

If a capacitor of 0.0010000 μF is put in place of the inductor, the resulting complex impedance at 4.0000 MHz is:

$$Z_{RC} = R - jX_C = 100.00 - j39.789$$

If all three components are connected in series, then the reactances add, yielding a complex impedance of:

$$Z_{RLC} = 100 + j251.33 - j39.789 = 100 + j211.5$$

This is the equivalent of a 100-ohm resistor in series with an inductor having $+j211.5$ ohms of reactance. At 4.0000 MHz, this reactance is presented by an inductance of 8.415 μH , as determined by plugging the numbers into the formula for inductive reactance and working backwards. (See the definition of ω for this formula, and for the corresponding formula for capacitive reactance.)

Parallel RLC circuits are more complicated to analyze than are series circuits. To calculate the effects of capacitive and inductive reactance in parallel, the quantities are converted to *inductive susceptance* and *capacitive susceptance*. Susceptance is the reciprocal of reactance. Susceptance combines with *conductance*, which is the reciprocal of resistance, to form *complex admittance*, which is the reciprocal of complex impedance. Entire volumes have been devoted to the theoretical and practical aspects of resistance, conductance, reactance, susceptance, impedance, and admittance. An intermediate electronics text or reference book is recommended for further study.

impression

In Web advertising, the term *impression* is sometimes used as a synonym for *view*, as in *ad view*. Online publishers offer and their customers buy advertising measured in terms of ad views or impressions. Since a single Web page can contain multiple ads (depending on its design), a site usually registers more ad views per unit of time than Web pages per unit of time. (*Hits* is the term for any requested file, including each of a page's images. Although hits are of interest for traffic measurement purposes, they have no significance for advertisers.)

Page or ad impressions are logged in a log that is maintained by the site server. Programs like Web Trends read the log, abstract meaning from it, and generate a report about site usage. Other programs, such as Central Ad, can keep track of all ad impressions that have been sent and how many of these were clicked on by users.

IMT-2000 direct spread

See "WCDMA"

in the wild

According to noted computer **virus** expert Paul Ducklin, in order for a virus to be considered *in the wild*, "it must be spreading as a result of normal day-to-day operations on and between the computers of unsuspecting users." Although there are an estimated 47,000 computer viruses, fewer than 600 are said to be circulating outside of laboratories and research facilities—hence, in the wild. Experts say these wild viruses pose the most significant threat to computers. Wild viruses typically contain a damaging **payload** and the ability to wipe out all computer files, sometimes even damaging a computer's **BIOS**.

The Wild List Organization International has compiled a cumulative list of viruses considered to be in the wild. New viral strains are added as they are reported and can be verified. Recent examples of computer viruses in the wild include **Melissa**, **CIH**, and **W.32 Navidad** (the **Kriz virus**).

in-band signaling

In the public switched telephone network, (**PSTN**), in-band signaling is the exchange of **signaling** (call control) information on the same **channel** that the telephone call itself is using. Today, most long-distance communication uses **out-of-band signaling** as specified in various Signaling System 7 (**SS7**) standards.

incubator

In the business world, an incubator is an enterprise that is set up to provide office space, equipment, and sometimes mentoring assistance and capital to new businesses that are just getting started. (The term is familiar in poultry farming, where an incubator is a specially-equipped home for baby chickens.) Business incubators are set up by universities, non-profit groups, and increasingly by venture capitalists, especially for new Web businesses.

On the Web, the pace of growth and competition, especially of retail and business-to-business (**B2B**) Web sites, is fostering software packages for the creation of "out-of-the-box" Web sites. For more ambitious Web sites and technology product development, venture capitalists are discovering that the incubation idea provides an organized way to finance and monitor the progress of its fledgling "chicks."

In early 2000, the number of incubators in the U.S. was approaching 1,000, with the largest located in major cities and many university-sponsored incubators scattered throughout the country. There are also incubators in the UK and elsewhere.

incumbent local exchange carrier

See "TLEC"

Indefeasible Right of Use

In telecommunications, Indefeasible Right of Use (IRU) is the effective long-term lease (temporary ownership) of a portion of the capacity of an international cable. IRUs are specified in terms of a certain number of **channels** of a given **bandwidth**. IRU is granted by the company or consortium of companies that built the (usually **optical fiber**) cable. Some IRU legal agreements forbid resale of the capacity ownership. For at least one major international cable owner, an IRU ownership period is granted for 25 years.

An IRU gives a large-scale Internet service provider (**ISP**) the ability to assure its own customers of international service on a long-term basis.

Indeo

Indeo is a **compression** algorithm developed by Intel and used by Microsoft's Video for Windows.

Other digital video compression algorithms include **MPEG** and **PLV**.

independent software vendor

See "ISV"

Indexed Sequential Access Method

See "ISAM"

inductance

See "inductor"

inductor

An inductor is a passive electronic component that stores energy in the form of a magnetic field. In its simplest form, an inductor consists of a wire loop or coil. The inductance is directly proportional to the number of turns in the coil. Inductance also depends on the radius of the coil and on the type of material around which the coil is wound.

For a given coil radius and number of turns, air cores result in the least inductance. **Dielectric** materials such as wood, glass, and plastic are essentially the same as air for the purposes of inductor winding. Ferromagnetic substances such as iron, laminated iron, and powdered iron increase the inductance obtainable with a coil having a given number of turns. In some cases, this increase is on the order of thousands of times. The shape of the core is also significant. Toroidal (donut-shaped) cores provide more inductance, for a given core material and number of turns, than solenoidal (rod-shaped) cores.

The standard unit of inductance is the **henry**, abbreviated H. This is a large unit. More common units are the microhenry, abbreviated μH ($1 \mu\text{H} = 10^{-6}\text{H}$) and the millihenry, abbreviated mH ($1 \text{mH} = 10^{-3} \text{H}$). Occasionally, the nanohenry (nH) is used ($1 \text{nH} = 10^{-9} \text{H}$).

It is difficult to fabricate inductors onto integrated circuit (IC) chips. Fortunately, **resistors** can be substituted for inductors in most microcircuit applications. In some cases, inductance can be simulated by simple electronic circuits using **transistors**, resistors, and **capacitors** fabricated onto IC chips.

Inductors are used with capacitors in various **wireless** communications applications. An inductor connected in series or parallel with a capacitor can provide discrimination against unwanted signals. Large inductors are used in the power supplies of electronic equipment of all types, including computers and their peripherals. In these systems, the inductors help to smooth out the rectified utility **AC**, providing pure, battery-like **DC**.

industrial strength

In information technology, *industrial strength* is the ability of a hardware or software product or a system to work capably and dependably in the operational world of business. Prior to the advent of today's information technology revolution, the term was used to describe such products as cleansers, lubricants, and stepladders.

In the world of **mainframe** computers, IBM's flagship **operating system**, **OS/390** (and its predecessor versions of **MVS**), has been described as having industrial strength.

Industry Standard Architecture

See "ISA"

InfiniBand

InfiniBand is an architecture and specification for data flow between processors and I/O devices that promises greater **bandwidth** and almost unlimited expandability in tomorrow's computer systems. In the next few years, InfiniBand is expected to gradually replace the existing Peripheral Component Interconnect (**PCI**) shared-bus approach used in most of today's personal computers and servers. Offering throughput of up to 2.5 **gigabytes** per second and support for up to 64,000 addressable devices, the architecture also promises increased reliability, better sharing of data between clustered processors, and built-in security. InfiniBand is the result of merging two competing designs, Future I/O, developed by Compaq, IBM, and Hewlett-Packard, with Next Generation I/O, developed by Intel, Microsoft, and Sun Microsystems. For a short time before the group came up with a new name, InfiniBand was called System I/O.

Existing PCs and server systems are hampered with an inflexible and relatively slow internal data flow system, including today's 64-bit, 66 **MHz** PCI bus. As the amount of data coming into and flowing between components in the computer increases, the existing bus system becomes a bottleneck. InfiniBand provides a revolutionary new approach. Instead of sending data in parallel (typically 32 bits at a time, but in some computers 64 bits) across the **backplane** bus (data path), InfiniBand specifies a serial (bit-at-a-time) bus. Fewer **pins** and other electrical connections are required, saving manufacturing cost and improving reliability. The serial bus can carry multiple **channels** of data at the same time in a **multiplexing** signal. InfiniBand also supports multiple **memory** areas, each of which can be addressed by both processors and storage devices.

Unlike the present I/O subsystem in a computer, InfiniBand seems like a full-fledged network. The InfiniBand Trade Organization describes the new bus as an I/O network and views the bus itself as a **switch** since control information will determine the route a given message follows in getting to its destination address. In fact, InfiniBand uses Internet Protocol Version 6 (**IPv6**) with its 128-bit address, allowing an almost limitless amount of device expansion.

With InfiniBand, data is transmitted in **packets** that together form a communication called a *message*. A message can be a remote direct memory access (RDMA) read or write operation, a channel send or receive message, a transaction-based operation (that can be reversed), or a **multicast** transmission. Like the channel model many mainframe users are familiar with, all transmission begins or ends with a channel adapter. Each processor (your PC or a data center server, for example) has what is called a *host channel adapter* (**HCA**) and each peripheral device has a *target channel adapter* (**TCA**). These adapters can potentially exchange information that ensures security or work with a given Quality of Service level.

infomediary

An infomediary is a **Web site** that provides specialized information on behalf of producers of goods and services and their potential customers. The term is a composite of *information* and *intermediary*. The advent of the Web has made possible quick 24-hour access to information databases that previously were not available. Gathering these information aggregates and adding services to them is now the business of companies like the Thomas Register of Manufacturers that can bring a base of information from the print medium to the Web. Perhaps more importantly as infomediaries are Web sites that are gathering, organizing, and linking to the new information and services that is being added to the Web.

Infomediaries can be divided into those intended for consumers and those intended for businesses. Any consumer **e-commerce** site that provides information as well as an order form could be classed as an infomediary. However, the term is more frequently used to refer to sites that offer information for businesses about suppliers and other businesses.

infomercial

On television, an infomercial is a short or regular-length television program that combines information presentation with an integrated suggestion to buy a particular product or service. Exercise equipment and correspondence courses are two products sometimes sold through infomercials.

In the print media, the equivalent to an infomercial is the multi-page "advertising supplement" that is formatted to look like the news part of the medium and contains real information content.

The Internet analog of the infomercial appears to be what advertisers generally refer to as "rich media," including interactive banner ads that sometimes include **Flash** animations.

Similar neologisms include **infotainment** and **edutainment**.

infonesia

Infonesia is an inability to remember where you saw or heard an item of information. The condition is usually temporary but can recur frequently. It is more common in "information societies", with their flows of **e-mail**, seasonal catalogs, **personal digital assistants**, and trial magazine subscriptions. Possibly the most pernicious form of infonesia is **internesia**, the inability to remember which Web site you saw an item of information on.

A person who is racking their brain to remember the information source could properly be termed an infonesiac, although this usage is not common.

information

Information is stimuli that has meaning in some context for its receiver. Some (if not all) kinds of information can be converted into **data** and passed on to another receiver. Relative to the computer, we can say that: Information is made into data, put into the computer where it is stored and processed as data, and then put out as data in some form that can be perceived as information.

Knowledge is information that is readily accessible to its user (for example, either in one's brain or in a nearby dictionary).

Information and Content Exchange

Information and Content Exchange (ICE) is an **XML**-based standard **protocol** for electronic business-to-business (**B2B**) asset management. ICE defines an architecture and a common language that can be used as a means of automating Web content **syndication** (information sharing and reuse between Web sites) for publishing and **e-commerce** uses. Members of the ICE Authoring Group (which includes representatives from Adobe Systems, Microsoft, Sun Microsystems, Vignette, and National Semiconductor) are committed to the further development of ICE as an **open** standard. ICE version 1.1 was released in June 2000.

ICE enables the automation of data supplying, exchanging, updating, and controlling without requiring the supplier to manually package content, or to maintain knowledge about the structure of recipient Web sites. ICE specifies creation of a trust relationship based on the Open Profiling System (**OPS**). Use of the ICE protocol enables data sharing between servers, so that, for example, syndicated portions of a Web page can be automatically updated when the source is updated, or new content can be automatically entered and integrated with existing content on a Web page. Each protocol message between servers consists of a valid (conforming to **namespace** criteria) XML document. XML **tags** are used to format data to be processed by the servers involved in the transaction.

ICE is intended to make it possible for almost every aspect of B2B asset exchange to be automated. Use of the protocol allows information service providers to specify content, customize it for specific recipients, schedule its delivery, and maintain it. Nevertheless, the success of content syndication is still reliant on the development of a standard **metadata** vocabulary, considered to be another essential element. The Publishing Requirements for Industry Standard Metadata (PRISM) working group (an organization made up of content providers and vendors) is collaborating to develop such a standard.

information architecture

1) In technical writing, information architecture is the set of ideas about how all information in a given context should be treated philosophically and, in a general way, how it should be organized. In the context of a company making computer products, an information architect might say that "All of our product information should serve customer needs as expressed by tasks that they have to do with our products," and would then develop a framework for organizing all existing and future product information in modules related to customer tasks. The results of this thinking would be expressed in an information architecture document.

For product information in the example just discussed, the information architecture document would become the foundation for *information planning*, which focuses on using the architecture for a specific division, set of products, or individual product. In addition to information architecture and information planning, **information design** focuses more narrowly on activities that support the architecture and planning, such as style guidelines, graphic design motifs, page design, and the information aspects of industrial design (labels, knobs, and other physical aspects of the user interface).

2) In Web site design, information architecture has a meaning similar to (1), but focused somewhat more narrowly on Web content as building blocks to be fit into a site's visual design and navigation scheme.

In technical writing in general and in Web site design in particular, information architecture is related to and generally supports the overlapping areas of **content management**, **content distribution** or **syndication**, and **electronic publishing**. Information architecture is also related to the treatment of information modules or building blocks as "objects" that can be described in one or a set of data definitions, typically using the Extensible Markup Language (XML). For example, an encyclopedic topic could be treated as a building block that could be distributed electronically using an XML definition that described each of the items in the topic (title, main content, author, date of authorship, and so forth).

information design

Information design is the detailed planning of specific **information** that is to be provided to a particular audience to meet specific objectives. The information designer may or may not have available (or may create) an information architecture that defines the overall pattern or structure that is imposed on the information design and an information plan that defines information units and how they are to be completed. The output of an information design is sometimes expressed in written instructions, plans, sketches, drawings, or formal specifications. However, on very small projects, information design is likely to be much less formal.

Information design can be distinguished from *information architecture* and *information planning*. In one view, there are three hierarchical levels of activity:

1. *Information architecture*, which is the general set of ideas about how all information in a given context should be organized. For example, one might say that "All of our product information should serve customer needs as expressed by tasks they have to do with our products," and then develop a pattern that organizes all product information in modules related to customer tasks. The output is an information architecture document.

2. *Information planning*, which focuses on all aspects required to prepare and support the information of a specific set of products, single product, or event over the product life or other time span. This generally includes understanding the product or event goals, studying the audience and their needs, considering possible information media, defining specific information "units" (books, chapters, Web pages, visualizations, and so forth), specifying the people who will work on them, what the schedule is, and how this work will relate to the work of others. The output is an information plan.
3. *Information design*, which focuses more narrowly on the information itself in one or more information units, and may encompass the information aspects of industrial design (labels, knobs, and the physical interface), information content design, page design, Web site design, illustration design, typography decisions, and so forth. Information design can be applied to a single work, such as a city map, or to a corporation's entire set of customer information. The output may be part of an information plan, a separate information design document, or simply the designed object or set of objects.

Information design ideas can often be tested in a usability laboratory by observing surrogate users trying to use the designed information and getting their feedback. The practice of information design invites questions into how people learn or prefer to learn and how they use information. It also raises questions about how to design information for different cultural and other contextual differences in the audience.

Since information is now commonly delivered using electronic media with new possibilities for user interaction and as product designers have become more aware of the importance of usability, a new term, *interaction design*, has arisen as a corollary of information design. A number of universities now offer courses or degree programs centered on information design.

infosurfing

Infosurfing is using the Internet and World Wide Web so that you get maximum information in the shortest amount of time, which for many people means favoring textual content over images. Infosurfing is practiced by librarians, professional researchers, journalists, people addicted to news, and almost anyone that gets impatient with multimedia or likes the focus of just plain text.

The simplest way to infosurf is to turn the pictures (images) off, using your browser option. Many sites specify an alternate text string in the HTML image tag that provides a brief textual description of each image in the space allocated for it. Otherwise, you'll get a broken image icon from your browser. Turning off graphics is best when you're familiar with most sites and know what you're missing.

Some infosurfers also turn off Java and JavaScript, turning them back on only when wanted. Once you get the idea of turning things off, some infosurfers also turn off **cookie** though cookies don't in themselves impede the downloading of text. If you have the latest levels of Netscape Communicator and Microsoft Internet Explorer, you can specify that cookies be disabled entirely or that you be prompted about whether to accept one.

If you infosurf for certain kinds of information, you'll obviously want to bookmark the sites that specialize in what you're interested in. You may want to subscribe to e-mail newsletters such as those at ZDNet, Women's Wire, or *whatis.com*. These newsletters summarize stories you can choose to link to or not.

Other techniques include: opening the browser several times and looking in one window while downloading to another and increasing the size of your browser **cache**. If you're constantly checking the latest news, you might set your start page at a news site. If you like to learn new words every day, you might start with *whatis*.

infotainment

Infotainment, combining *information* with *entertainment*, is a fairly recent **neologism** for a television program, Web site feature, or other presentation that combines information with entertainment. Most of today's popular fact-based television shows, such as those on the Animal Planet channel, could be classed as infotainment.

Serious information publishing sites such as those of TechTarget.com (including *whatis.com*) provide a limited amount of infotainment in the form of user polls, quizzes, and contests.

Also see **infomercial** and **edutainment**.

infranet

Infranet is a term used to refer to the **infrastructure** of a **network**, especially the **Internet**. For the Internet, the infranet is that portion of the public telephone network on which data **packets** are exchanged using Internet **protocols**. It can also be said to include private network infrastructures that use the Internet set of protocols, **TCP/IP**, whether or not these interconnect with the public Internet. The term was used to describe the major **switching** hardware and technologies, such as **frame relay** and **asynchronous transfer mode**, in an April 1999 article, "The Next Net," in *Wired* magazine. John Chambers, head of Cisco Systems, is credited with coining the term.

infrared radiation

Infrared radiation (IR) or the term *infrared* alone refers to energy in the region of the **electromagnetic radiation spectrum** at wavelengths longer than those of visible light, but shorter than those of radio waves. Correspondingly, the frequencies of IR are higher than those of microwaves, but lower than those of visible light.

Scientists divide the IR spectrum into three regions. The wavelengths are specified in microns (symbolized μ , where $1 \mu = 10^{-6}$ meter) or in nanometers (abbreviated nm, where $1 \text{ nm} = 10^{-9}$ meter = 0.001μ). The *near IR band* contains energy in the range of wavelengths closest to the visible, from approximately 0.750 to 1.300 μ (750 to 1300 nm). The *intermediate IR band* (also called the *middle IR band*) consists of energy in the range 1.300 to 3.000 μ (1300 to 3000 nm). The *far IR band* extends from 2.000 to 14.000 μ (3000 nm to 1.4000×10^4 nm).

Infrared is used in a variety of **wireless** communications, monitoring, and control applications. A few of the applications include home-entertainment remote-control boxes, wireless local area networks, links between notebook computers and desktop computers, cordless **modems**, intrusion detectors, motion detectors, and fire sensors.

infrastructure

In information technology and on the Internet, infrastructure is the physical **hardware** used to interconnect **computers** and users. Infrastructure includes the transmission media, including telephone lines, cable television lines, and **satellites** and antennas, and also the **routers**, **aggregators**, **repeaters**, and other devices that control transmission paths. Infrastructure also includes the **software** used to send, receive, and manage the **signals** that are transmitted.

In some usages, infrastructure refers to interconnecting hardware and software and not to computers and other devices that are interconnected. However, to some information technology users, infrastructure is viewed as everything that supports the flow and processing of information.

Infrastructure companies play a significant part in evolving the Internet, both in terms of where the interconnections are placed and made accessible and in terms of how much information can be carried how quickly.

Ingress

Ingress (pronounced IHN-grehs, from Latin *ingressus* or stepping into) is the act of entering something. For example, in telecommunications, an ingress router is a **router** through which a data packet enters a network from another network.

Inheritance

In **object-oriented programming**, inheritance is the concept that when a **class of objects** is defined, any subclass that is defined can inherit the definitions of one or more general classes. This means for the programmer that an object in a subclass need not carry its own definition of data and methods that are generic to the class (or classes) of which it is a part. This not only speeds up program development; it also ensures an inherent validity to the defined subclass object (what works and is consistent about the class will also work for the subclass).

Initial public offering

See “IPO”

Initialization

Initialization is the process of locating and using the defined values for variable **data** that is used by a computer program. For example, an **operating system** or application program is installed with **defaults** or user-specified values that determine certain aspects of how the system or program is to function. Typically, these values are stored in initialization files (in Windows, these can be identified as files with an INI suffix). When the operating system or an application program is first loaded into memory, a part of the program performs initialization—that is, it looks in the initialization files, finds definite values to substitute for variable values, and acts accordingly. For example, the desktop appearance and application programs that are to be started along with the operating system are identified and loaded.

The process of the user specifying initialization values is sometimes called *configuration*.

Inode

In a **UNIX-based operating system**, an inode is a computer-stored description of an individual file in a UNIX file system.

Insect robot

See “robot”

InstallAnywhere

InstallAnywhere is a program that can be used by software developers to package a product written in **Java** so that it can be installed on any major **operating system**. As its name indicates, a big advantage of InstallAnywhere is that the developer does not have to package different distribution versions of a product for different operating systems. InstallAnywhere refers to this idea as a “universal installer.” The idea is possible because programs written in **Java** can be compiled into Java **bytecode** that is independent of operating system differences. Since major operating systems today come with a Java, one InstallAnywhere-packaged Java-based product will install on any of the systems.

InstallAnywhere is intended to be easy for developers to use. Customized installers will **deploy** a package from the Web or CD-ROM. An InstallAnywhere-packaged Java-based product will install on Windows 95/98/NT, Solaris, Linux, AIX, HP-UX, IRIX, OS/2 and any other Java-enabled platform.

Installfest

An Installfest is a special occasion when computer users get together to help each other install new programming, usually the **Linux operating system** and related programs, often together with experts and the resources to download programming from the Internet. The Installfest idea was originated by Linux enthusiasts and has been well supported by Linux distributors, which include Red Hat, S. U. S. E., Slackware, Debian, and Caldera. Typically, an Installfest is sponsored by a local computer club. The Installfest idea has caught on, and, at some computer club meetings, the Installfest is an ongoing part of each regular meeting.

InstallShield

InstallShield is a product used by software developers to package software so that users can install it easily and safely. (It can also be used to uninstall a product.)

InstallShield provides the developer with templates and pre-built interface objects that make it easy to package the software. Users who receive software packaged with InstallShield are assured that it will be installed quickly and without affecting other applications or system characteristics.

instant messaging

See also **IRC** (Internet Relay Chat) and **ICQ** (I Seek You).

Instant messaging (sometimes called IM or IMing) is the ability to easily see whether a chosen friend or co-worker is connected to the Internet and, if they are, to exchange messages with them. Instant messaging differs from ordinary **e-mail** in the immediacy of the message exchange and also makes a continued exchange simpler than sending e-mail back and forth. Most exchanges are text-only. However, some services allow attachments. AOL first popularized instant messaging and, with its large membership, is likely to be the most popular service for some time to come. AOL's Instant Messenger can be used by AOL members but there is no requirement to be connected to the Internet through AOL. An **Open Source** alternative to AOL's instant messaging is called **Jabber**.

In order for IMing to work, both users (who must subscribe to the service) must be online at the same time, and the intended recipient must be willing to accept instant messages. (It is possible to set your software to reject messages.) An attempt to send an IM to someone who is not online, or who is not willing to accept IMs, will result in notification that the transmission cannot be completed. If the online software is set to accept IMs, it alerts the recipient with a distinctive sound, a window that indicates that an IM has arrived and allowing the recipient to accept or reject it, or a window containing the incoming message.

Under most conditions, IMing is truly "instant." Even during peak Internet usage periods, the delay is rarely more than a second or two. It is possible for two people to have a real-time online "conversation" by IMing each other back and forth.

instant translation

Also see **automatic language translation**.

Instant translation is the translation from one language to another of Web pages, e-mail, and online chat text by a computer program so that the translated results appear almost instantly. Instant translation services are gaining in popularity because they help people who work for global businesses communicate and enable e-commerce sites to appeal to customers in other countries. Because much of the material on the Web is written in English and the majority of the world speaks other languages, most instant translation is from English to another language. IDC estimates that the machine translation industry will grow to \$378 million by 2003.

Most instant translation tools store frequently-encountered words, sentences, and phrases in a database that is accessed when a new document is translated. Until recently, vendors like Lernout & Hauspie, Systran, and Transparent Language dominated the instant translation space. However, IBM is entering the arena with the WebSphere Translation Server,

targeting Internet service providers and other companies that run their own servers. The IBM product creates and distributes Web content globally without the need for special Web pages or separate infrastructure. WebSphere Translation Server translates material from English to French, Spanish, German, Italian, Chinese, Japanese, and Korean but does not convert material into English.

Some companies are especially cautious when using instant translation software, having discovered that even small translation errors can result in big business problems.

instantiate

An instance is a particular realization of an abstraction or **template** such as a **class of objects** or a computer **process**. To instantiate is to create such an instance by, for example, defining one particular variation of object within a class, giving it a name, and locating it in some physical place.

1) In **object-oriented programming**, some writers say that you instantiate a **class** to create an **object**, a concrete instance of the class. The object is an executable file that you can run in a computer.

2) In the object-oriented programming language, **Java**, the object that you instantiate from a class is, confusingly enough, called a class instead of an object. In other words, using Java, you instantiate a class to create a specific class that is also an executable file you can run in a computer.

3) In approaches to data modeling and programming prior to object-oriented programming, one usage of *instantiate* was to make a real (data-filled) object from an abstract object as you would do by creating an entry in a table (which, when empty, can be thought of as a kind of class template for the objects to be filled in).

Institute of Electrical and Electronics Engineers

See "IEEE"

instruction

An instruction is an order given to a **computer processor** by a computer **program**. At the lowest level, each instruction is a sequence of 0s and 1s that describes a physical operation the computer is to perform (such as "Add") and, depending on the particular instruction type, the specification of special storage areas called "registers" that may contain data that to be used in carrying out the instruction or the location in computer **memory** of data that is to be used in carrying out the instruction, or a direct or indirect reference to the location in memory of the data.

In a computer's **assembler** language, each language statement generally corresponds to a single processor instruction. In higher-level languages, a language statement generally results (after program compilation) in multiple processor instructions.

In assembler language, a “macro instruction” is one that, during processing by the assembler program, expands to become multiple instructions (based on a previously coded “macro definition”).

int

“int” is one of the top-level **domain names** that can be used when choosing a domain name. This domain name is intended for sites related to international treaties or containing international databases. (For this reason, the domain name is not widely used.) Along with the second-level domain name, the top-level domain name is required in Web and e-mail addresses.

For more information, see **gTLD** (generic top-level domain name).

integer

An integer (pronounced IN-tuh-ger) is a whole number (not a fractional number) that can be positive, negative, or zero.

Examples of integers are: -5, 1, 5, 8, 97, and 3,043.

Examples of numbers that are not integers are: -1.43, 1^{3/4}, 3.14, .09, and 5,643.1.

The set of integers, denoted **Z**, is formally defined as follows:

$$Z = \{ \dots, -3, -2, -1, 0, 1, 2, 3, \dots \}$$

In mathematical equations, unknown or unspecified integers are represented by lowercase, italicized letters from the “late middle” of the alphabet. The most common are *p*, *q*, *r*, and *s*.

The set **Z** is a *denumerable* set. Denumerability refers to the fact that, even though there might be an infinite number of elements in a set, those elements can be denoted by a list that implies the identity of every element in the set. For example, it is intuitive from the list {..., -3, -2, -1, 0, 1, 2, 3, ...} that 356,804,251 and -67,332 are integers, but 356,804,251.5, -67,332.89, -4^{1/3}, and 0.232323 ... are not.

The elements of **Z** can be paired off one-to-one with the elements of **N**, the set of natural numbers, with no elements being left out of either set. Let **N** = {1, 2, 3, ...}. Then the pairing can proceed in this way:

In infinite sets, the existence of a one-to-one correspondence is the litmus test for determining **cardinality**, or size. The set of natural numbers and the set of rational numbers have the same cardinality as **Z**. However, the sets of real numbers, imaginary numbers, and complex numbers have cardinality larger than that of **Z**.

integrated circuit

An integrated circuit (IC), sometimes called a *chip* or **microchip**, is a **semiconductor** wafer on which thousands or millions of tiny resistors, **capacitors**, and **transistors** are fabricated. An IC can function as an **amplifier**, **oscillator**, timer, counter, computer **memory**, or **microprocessor**. A particular IC is categorized as either linear (**analog**) or **digital**, depending on its intended application.

Linear ICs have continuously variable output (theoretically capable of attaining an infinite number of states) that depends on the input signal level. As the term implies, the output signal level is a linear function of the input signal level. Ideally, when the instantaneous output is graphed against the instantaneous input, the plot appears as a straight line. Linear ICs are used as audio-frequency (**AF**) and radio-frequency (**RF**) amplifiers. The *operational amplifier* (op amp) is a common device in these applications.

Digital ICs operate at only a few defined levels or states, rather than over a continuous range of signal amplitudes. These devices are used in computers, computer networks, modems, and frequency counters. **Logic gates** are the fundamental building blocks of digital ICs that work with binary data, that is, signals that have only two different states, called low (logic 0) and high (logic 1).

integrated development environment

(The abbreviation *IDE* also stands for **Integrated Drive Electronics**.)

An integrated development environment (IDE) is a programming environment that has been packaged as an application program, typically consisting of a code editor, a **compiler**, a debugger, and a graphical user interface (**GUI**) builder. The IDE may be a standalone application or may be included as part of one or more existing and compatible applications. The **BASIC** programming language, for example, can be used within Microsoft Office applications, which makes it possible to write a WordBasic program within the Microsoft Word application. IDEs provide a user-friendly framework for many modern programming languages, such as **Visual Basic**, **Java**, and **PowerBuilder**.

IDEs for developing **HTML** applications are among the most commonly used. For example, many people designing Web sites today use an IDE (such as HomeSite, DreamWeaver, or FrontPage) for Web site development that automates many of the tasks involved.

Integrated Digital Enhanced Network

See “iDEN”

Integrated Drive Electronics

See “IDE”

Integrated Services Digital Network

See "ISDN"

integration

Integration (from the Latin *integer*, meaning whole or entire) generally means combining parts so that they work together or form a whole. In information technology, there are several common usages:

- 1) Integration during product development is a process in which separately produced components or subsystems are combined and problems in their interactions are addressed.
- 2) Integration is an activity by companies that specialize in bringing different manufacturers' products together into a smoothly working system.
- 3) In marketing usage, products or components said to be integrated appear to meet one or more of the following conditions:

- A) They share a common purpose or set of objectives. (This is the loosest form of integration.)
- B) They all observe the same standard or set of standard **protocols** or they share a mediating capability, such the Object Request Broker (**ORB**) in the Common Object Request Broker Architecture (**CORBA**).
- C) They were all designed together at the same time with a unifying purpose and/or architecture. (They may be sold as piece-parts but they were designed with the same larger objectives and/or architecture.)
- D) They share some of the same programming code.
- E) They share some special knowledge of code (such as a lower-level program interface) that may or may not be publicly available. (If not publicly available, companies have been known to sue to make it available in order to make competition fair.)

In describing its Internet Information Manager (**IIS**), Microsoft says that it is "tightly integrated," apparently meaning that it meets conditions (A), (B), to some extent (C), possibly a bit of (D), and, if any, an unstated amount of (E).

integrity

Integrity, in terms of data and network security, is the assurance that information can only be accessed or modified by those authorized to do so. Measures taken to ensure integrity include controlling the physical environment of networked terminals and servers, restricting access to data, and maintaining rigorous **authentication** practices. Data integrity can also be threatened by environmental hazards, such as heat, dust, and electrical surges.

Practices followed to protect data integrity in the physical environment include: Making servers accessible only to network administrators, keeping transmission media (such as cables and connectors) covered and protected to ensure

that they cannot be tapped, and protecting hardware and storage media from power surges, electrostatic discharges, and magnetism.

Network administration measures to ensure data integrity include: maintaining current authorization levels for all users, documenting system administration procedures, parameters, and maintenance activities, and creating disaster recovery plans for occurrences such as power outages, server failure, and virus attacks.

intellectual capital

Intellectual capital is **knowledge** that can be exploited for some money-making or other useful purpose. The term combines the idea of the intellect or brain-power with the economic concept of capital, the saving of entitled benefits so that they can be invested in producing more goods and services. Intellectual capital can include the skills and knowledge that a company has developed about how to make its goods or services; individual employees or groups of employees whose knowledge is deemed critical to a company's continued success; and its aggregation of documents about processes, customers, research results, and other information that might have value for a competitor that is not common knowledge.

intelligent agent

On the Internet, an intelligent agent (or simply an *agent*) is a program that gathers information or performs some other service without your immediate presence and on some regular schedule. Typically, an agent program, using parameters you have provided, searches all or some part of the Internet, gathers information you're interested in, and presents it to you on a daily or other periodic basis. An agent is sometimes called a **bot** (short for robot).

Other agents have been developed that personalize information on a Web site based on registration information and usage analysis. Other types of agents include specific site watchers that tell you when the site has been updated or look for other events and analyst agents that not only gather but organize and interpret information for you.

The practice or technology of having information brought to you by an agent is sometimes referred to as **push** technology.

Intelligent Network

Intelligent Network (IN) is a telephone network architecture originated by Bell Communications Research (Bellcore) in which the service logic for a call is located separately from the switching facilities, allowing services to be added or changed without having to redesign switching equipment. According to Bell Atlantic, IN is a "service-specific" architecture. That is, a certain portion of a dialed phone number, such as 800 or 900, triggers a request for a specific service. A later version of IN called Advanced Intelligent

Network (AIN) introduces the idea of a “service-independent” architecture in which a given part of a telephone number can be interpreted differently by different services depending on factors such as time of day, caller identity, and type of call. AIN makes it easy to add new services without having to install new phone equipment.

Bellcore called its network IN/1. It included this model:

- The customer’s telephone
- The switching system (starting with the switch a call is handled by first, usually at a telephone company central office (CO))
- A database called a service control point (SCP) that defines the possible services and their logic
- A service management system (SMS)

For more information, see AIN.

intelligent peripheral interface

See “IPI”

Interactive System Productivity Facility

See “ISPF”

interactive TV

Interactive TV means allowing the viewer to interact with the television set in ways other than simply controlling the channel and the volume and handling videotapes. Typical interactive TV uses are selecting a video film to view from a central bank of films, playing games, voting or providing other immediate feedback through the television connection, banking from home, and shopping from home.

Interactive TV involves adding a special “set-top unit” to the existing television set. In addition, other installation and infrastructure arrangements are required, depending on the particular approach. Most services involve offering special programming, news, and home shopping and a number offer video-on-demand and home banking. Since interactive TV still requires a considerable investment by both the service provider and the consumer and because interactive applications are still being explored, it is somewhat difficult to predict how soon it will become widely deployed.

Interactive Voice Response

Interactive Voice Response (IVR) is a software application that accepts a combination of voice telephone input and touch-tone keypad selection and provides appropriate responses in the form of voice, fax, callback, e-mail and perhaps other media. IVR is usually part of a larger application that includes **database** access. Common IVR applications include:

- Bank and stock account balances and transfers
- Surveys and polls

- Call center forwarding
- Simple order entry transactions
- Selective information lookup (movie schedules, etc.)

An IVR application provides pre-recorded voice responses for appropriate situations, keypad signal logic, access to relevant data, and potentially the ability to record voice input for later handling. Using computer telephony integration (CTI), IVR applications can hand off a call to a human being who can view data related to the caller at a display.

interactivity

In computers, interactivity is the sensory dialog that occurs between a human being (or possibly another live creature) and a computer **program**. (Programs that run without immediate user involvement are not interactive; they’re usually called **batch** or background programs.) Games are usually thought of as fostering a great amount of interactivity. However, order entry applications and many other business applications are also interactive, but in a more constrained way (offering fewer options for user interaction).

On the World Wide Web, you not only interact with the **browser** (the Web application program) but also with the pages that the browser brings to you. **Hypertext** or the word and picture links you can connect to are the most common form of interactivity when using the Web (which can be thought of as a giant, interconnected application program).

In addition to hypertext, the Web (and many non-Web applications in any computer system) offer other possibilities for interactivity. Any kind of user input, including typing commands or clicking the mouse, is a form of input. Displayed images and text, printouts, motion video sequences, and sounds are output forms of interactivity.

The earliest form of interaction with computers was indirect and consisted of submitting commands on punched cards and letting the computer read them and perform the commands. Later computer systems were designed so that average people (not just programmers) could interact immediately with computers, telling them what programs to run and then interacting with those programs, such as word processors (then called “editors”), drawing programs, and other interactive programs. The first interactive human-computer interfaces tended to be input text sequences called “commands” (as in “DOS commands”) and terse one-line responses from the system.

In the late 1970’s, the first graphical user interfaces (GUI) emerged from the Xerox PARC Lab, found their way into the Apple McIntosh personal computer, and then into Microsoft’s Windows operating systems and thus into almost all personal computers available today. GUIs inherently promoted interactivity because they offered the user more interaction options.

interexchange carrier

An interexchange carrier (IXC) is a telephone company that provides connections between **local exchanges** in different geographic areas. IXCs provide *interLATA* service as described in the **Telecommunications Act of 1996**. They're commonly referred to as "long-distance carriers." IXCs include AT&T, MCI, Sprint, and others.

interface

As a noun, an interface is either:

1. A user interface, consisting of the set of dials, knobs, operating system commands, graphical display formats, and other devices provided by a computer or a program to allow the user to communicate and use the computer or program. A graphical user interface (**GUI**) provides its user a more or less "picture-oriented" way to interact with technology. A GUI is usually a more satisfying or user-friendly interface to a computer system.
2. A programming interface, consisting of the set of statements, functions, options, and other ways of expressing program instructions and data provided by a program or language for a programmer to use.
3. The physical and logical arrangement supporting the attachment of any device to a connector or to another device.

As a verb, to interface means to communicate with another person or object. With hardware equipment, to interface means making an appropriate physical connection so that two pieces of equipment can communicate or work together effectively.

interface device

An interface device (IDF) is a hardware component or system of components that allows a human being to interact with a computer, a telephone system, or other electronic information system. The term is often encountered in the mobile communication industry where designers are challenged to build the proper combination of portability, capability, and ease of use into the interface device. The overall set of characteristics provided by an interface device is often referred to as the *user interface* (and, for computers—at least, in more academic discussions—the human-computer interface or **HCI**). Today's desktop and notebook computers have what has come to be called a graphical user interface (**GUI**) to distinguish it from earlier, more limited interfaces such as the command line interface (**CLI**).

An interface device generally must include some form or forms of output interface, such as a display screen or audio signals, and some form or forms of input interface, such as buttons to push, a keyboard, a voice receiver, or a handwriting tablet. Harmonia, a company that makes a program for developing Web pages that can be formatted on

the fly for different kinds of interface devices, defines six generic classes of interface devices that characterize today's technology:

- **The personal computer** (desktop or notebook, abundant memory and external storage, keyboard, large display)
- **Handheld** (much smaller, still has a keyboard)
- **Palm** (smaller still, can fit in some pockets, handwriting is primary input interface, display very small and usually landscape rather than portrait)
- **Smart Phone** (digital cellular phone with little or no computing, accepts Wireless Markup Language-coded pages from Web servers)
- **Smart Pager** (also known as a *two-way pager*, has the ability to respond by pressing buttons or by using a tiny keyboard)
- **Standard Telephone** (voice and key input interface, no computer capability)
- **Hybrid** (often a combined phone and handheld computer)

If you are creating content for a human receiver, you need at least a general understanding of the type or types of interface devices that your audience may be using. The Extensible Markup Language (**XML**) is designed to allow Web or other content to be created independently of the type of interface device that may be used. An individual **style sheet** designed for specific interface device types can be created using the Extensible Stylesheet Language (**XSL**). Then, when a user requests a page, that user's interface device type can be recognized and the appropriate style sheet used to format the page that is sent. Harmonia has developed a User Interface Markup Language (**UIML**) that facilitates this process.

Inter-IC bus

See "I2C bus"

Interior Gateway Protocol

See "IGP"

interlaced display

An interlaced display is a cathode-ray tube (**CRT**) display in which the lines are scanned alternately in two interwoven rasterized lines.

In a CRT display, there are several hundred horizontal lines in a frame (full screen). These lines are scanned from left to right, and from top to bottom. The refresh rate (number of frames scanned per second) varies, but it is normally between 60 and 100 **hertz**. Refresh rates slower than 60 Hz produce distracting screen flicker, which can cause headaches and eye fatigue.

Most CRT computer monitors scan each line in turn from top to bottom at the lowest **resolution** levels (640 × 480 and 800 × 600 **pixel**). However, at the higher resolutions, such as 1024 × 768 or 1200 × 800, the frame is sometimes scanned in interlaced fashion: first the odd-numbered lines, and then the even-numbered lines. This allows for a lower refresh rate without producing flicker. With text and fixed graphics displays, this scheme can work well. However, with animated graphics—especially images that move or change form rapidly—interlacing can produce a fluttering effect at least as irritating as screen flicker.

For serious animated-graphics work and video editing, a non-interlaced CRT display is recommended. The refresh rate should be as high as the system will allow, ideally 70 Hz or more.

interlaced GIF

An interlaced GIF (**Graphics Interchange Format**) is a GIF image that seems to arrive on your display like an image coming through a slowly-opening Venetian blind. A fuzzy outline of an image is gradually replaced by seven successive waves of bit streams that fill in the missing lines until the image arrives at its full resolution. Among the advantages for the viewer using 14.4 Kbps and 28.8 Kbps modems are that the wait time for an image seems less and the viewer can sometimes get enough information about the image to decide to click on it or move elsewhere. For users with faster connections, there is little difference in effect between an interlaced GIF and a non-interlaced GIF.

intermediate distribution frame

IDF also stands for **interface device**.

An intermediate distribution frame (IDF) is a free-standing or wall-mounted rack for managing and interconnecting the telecommunications cable between end user devices and a main distribution frame (MDF). For example, an IDF might be located on each floor of a multi-floor building routing the cabling down the walls to an MDF on the first floor. The MDF would contain cabling that would interconnect to the phone company or to other buildings.

Intermediate System-to-Intermediate System protocol

See “IS-IS”

international callback

See “callback”

International Data Encryption Algorithm

IDEA (International Data Encryption Algorithm) is an **encryption algorithm** developed at ETH in Zurich, Switzerland. It uses a **block cipher** with a 128-bit **key**, and is generally considered to be very secure. It is considered

among the best publicly known algorithms. In the several years that it has been in use, no practical attacks on it have been published despite of a number of attempts to find some. IDEA is patented in the United States and in most of the European countries. The patent is held by Ascom-Tech. Non-commercial use of IDEA is free. Commercial licenses can be obtained by contacting Ascom-Tech.

International Electrotechnical Commission

On the Internet, “IEC” usually means the International Electrotechnical Commission.

In telephony, IEC may also refer to an “interexchange carrier” (a long-distance carrier).

International Organization for Standardization

See “ISO”

International Standard Book Number

See “ISBN”

International Standard Recording Code

The International Standard Recording Code (ISRC) is an international code used to identify sound and audio-visual recordings on compact discs (CDs), music videos, and other media, primarily to ensure royalty payments. ISRC was developed because of the need to reliably identify all recordings, especially digital recordings. ISRC was developed by the International Organization for Standardization (ISO) in 1986 and is also known as ISO 3901.

The ISRC code is contained in the subcode of each track or recording. The ISRC code is made up of letters and numbers and is 12 characters in length. The code consists of characters for the country, registrant, year of reference, and designation code separated by dashes. An example of an ISRC code is GB-Z03-01-53900.

The country code identifies the country of residence of the registrant of the recording such as the producer or owner. It consists of two letters that are allocated to each country by the ISO. For example, FR is the code for France. The registrant code identifies the producer of the recording. It consists of three characters, which contain both letters and numbers. The year of reference is the code that identifies the year in which the ISRC code was assigned to that recording. The code is the last two digits of the year. For 2001, the year of reference code is 01. The final code is the designation code. This code must be five digits in length and is assigned by the producer or owner of the recording.

An ISRC code may not be reused. For example, if a recording is remixed or the playing time changes, a new ISRC code must be assigned. The same ISRC code may be used if a

recording is sold or recompiled without any editing. The owner of the recording, copyright organizations, broadcasting organizations, and libraries use ISRC codes.

The ISO Technical Committee (TC) in charge of ISRC is ISO/TC 46.

International System of Units

The International System of Units (abbreviated "SI" from the French version of the name) is a scientific method of expressing the magnitudes or quantities of seven important natural phenomena. This system was formerly called the meter-kilogram-second (MKS) system.

All SI units can be expressed in terms of standard multiple or fractional quantities, as well as directly. Multiple and fractional SI units are defined by prefix multipliers according to powers of 10 ranging from 10^{-24} to 10^{24} .

Meter

The meter (abbreviation, m) is the SI unit of displacement or length. One meter is the distance traveled by a ray of electromagnetic (EM) energy through a vacuum in $1/299,792,458$ ($3.33564095 \times 10^{-9}$) second. The meter was originally defined as one ten-millionth (0.0000001 or 10^{-7}) of the distance, as measured over the earth's surface in a great circle passing through Paris, France, from the geographic north pole to the equator.

Kilogram

The kilogram (abbreviation, kg) is the SI unit of mass. It is defined as the mass of a particular international prototype made of platinum-iridium and kept at the International Bureau of Weights and Measures. It was originally defined as the mass of one liter (10^{-3} cubic meter) of pure water.

Second

The second (abbreviation, s or sec) is the SI unit of time. One second is the time that elapses during 9.192631770×10^9 cycles of the radiation produced by the transition between two levels of Cesium 133. It is also the time required for an EM field to propagate $299,792,458$ (2.99792458×10^8) meters through a vacuum.

Kelvin

The Kelvin (abbreviation K), also called the degree Kelvin (abbreviation, °K), is the SI unit of temperature. One Kelvin is $1/273.16$ (3.6609×10^{-3}) of the thermodynamic temperature of the triple point of pure water (H₂O).

Ampere

The ampere (abbreviation, A) is the SI unit of electric current. One ampere is the current that would produce a force of 0.0000002 (2×10^{-7}) newton between two straight, parallel, perfectly conducting wires having infinite length and zero diameter, separated by one meter in a vacuum. One ampere represents 6.24×10^{18} unit electric charge carriers, such as electrons, passing a specified fixed point in one second.

Candela

The candela (abbreviation, cd) is the SI unit of luminous intensity. It is the electromagnetic radiation, in a specified direction, that has an intensity of $1/683$ (1.46×10^{-3}) watt per steradian at a frequency of 540 terahertz (5.40×10^{14} hertz).

Mole

The mole (abbreviation, mol) is the SI unit of material quantity. One mole is the number of atoms in 0.012 kilogram of the most common isotope of elemental carbon (C-12). This is approximately 6.022169×10^{23} , and is also called the Avogadro constant.

Also see **prefix multipliers**.

internationalisation

See "internationalization"

internationalization

Internationalization (sometimes shortened to "I18N, meaning "I—eighteen letters -N") is the process of planning and implementing products and services so that they can easily be adapted to specific local languages and cultures, a process called **localization**. The internationalization process is sometimes called translation or localization *enablement*. Enablement can include:

- Allowing space in user interfaces (for example, hardware labels, help pages, and online menus) for translation into languages that require more characters
- Developing with products (such as Web editors or authoring tools) that can support international character sets (**Unicode**)
- Creating print or Web site graphic images so that their text labels can be translated inexpensively
- Using written examples that have global meaning
- For software, ensuring data space so that messages can be translated from languages with single-byte character codes (such as English) into languages requiring multiple-byte character codes (such as Japanese Kanji)

internesia

Internesia is an inability to remember which Web site or other Internet facility you saw an item of information on. It is an important form of the more general condition known as **infonesia**, which is the inability to remember where you saw an item of information from any source (newspapers, television, and so forth).

Infojunkies are especially susceptible to internesia. A person who can never remember a Web site is an internesiatic. Bookmarks may help, but many internesiatics bookmark so many sites, they can't find anything on their bookmark list or remember the right search word.

Internet

The Internet, sometimes called simply “the Net,” is a worldwide system of computer networks—a network of networks in which users at any one computer can, if they have permission, get information from any other computer (and sometimes talk directly to users at other computers). It was conceived by the Advanced Research Projects Agency (ARPA) of the U.S. government in 1969 and was first known as the **ARPANet**. The original aim was to create a network that would allow users of a research computer at one university to be able to “talk to” research computers at other universities. A side benefit of ARPANet’s design was that, because messages could be routed or rerouted in more than one direction, the network could continue to function even if parts of it were destroyed in the event of a military attack or other disaster.

Today, the Internet is a public, cooperative, and self-sustaining facility accessible to hundreds of millions of people worldwide. Physically, the Internet uses a portion of the total resources of the currently existing public telecommunication networks. Technically, what distinguishes the Internet is its use of a set of protocols called **TCP/IP** (for Transmission Control Protocol/Internet Protocol). Two recent adaptations of Internet technology, the **intranet** and the **extranet**, also make use of the TCP/IP protocol.

For many Internet users, electronic mail (**e-mail**) has practically replaced the Postal Service for short written transactions. Electronic mail is the most widely used application on the Net. You can also carry on live “conversations” with other computer users, using Internet Relay Chat (**IRC**). More recently, **Internet telephony** hardware and software allows real-time voice conversations.

The most widely used part of the Internet is the **World Wide Web** (often abbreviated “**WWW**” or called “the Web”). Its outstanding feature is **hypertext**, a method of instant cross-referencing. In most Web sites, certain words or phrases appear in text of a different color than the rest; often this text is also underlined. When you select one of these words or phrases, you will be transferred to the site or page that is relevant to this word or phrase. Sometimes there are buttons, images, or portions of images that are “clickable.” If you move the pointer over a spot on a Web site and the pointer changes into a hand, this indicates that you can click and be transferred to another site.

Using the Web, you have access to millions of pages of information. Web browsing is done with a Web **browser**, the most popular of which are Microsoft Internet Explorer and Netscape Navigator. The appearance of a particular Web site may vary slightly depending on the browser you use. Also, later versions of a particular browser are able to render more “bells and whistles” such as animation, virtual reality, sound, and music files, than earlier versions.

Internet access provider

See “IAP”

Internet Advertising Bureau

The IAB (Internet Advertising Bureau) is an organization that fosters the growth of advertising on the Internet. Membership is available to corporations engaged in selling, measuring, monitoring, or producing advertising on the Internet. The IAB recommends a set of standard-size banner ads for World Wide Web pages.

Internet Architecture Board

Internet Explorer Administration Kit

Internet Explorer Administration Kit (IEAK) is a product from Microsoft that enables an organization to centrally manage the customizing, deployment, and maintenance of Microsoft’s Web **browser**, Internet Explorer, for users on different computer **platforms**. There is no royalty on the deployed copies. Using IEAK, a company can set up every user’s browser the same way. Microsoft offers a step-by-step process for using the kit.

Internet Explorer

See “Microsoft Internet Explorer”

Internet Group Management Protocol

The Internet Group Management Protocol (IGMP) is an Internet **protocol** that provides a way for an Internet computer to report its **multicast** group membership to adjacent **routers**. Multicasting allows one computer on the Internet to send content to multiple other computers that

have identified themselves as interested in receiving the originating computer's content. Multicasting can be used for such applications as updating the address books of mobile computer users in the field, sending out company newsletters to a distribution list, and "broadcasting" high-bandwidth programs of **streaming media** to an audience that has "tuned in" by setting up a multicast group membership.

Using the Open Systems Interconnection (OSI) communication model, IGMP is part of the **Network layer**. IGMP is formally described in the Internet Engineering Task Force (IETF) Request for Comments (RFC) 2236.

Internet Information Server

See "IIS"

Internet Inter-ORB Protocol

See "IIOP"

Internet maps

Since the Internet began developing about 25 years ago, there has always been some kind of map showing what it looks like. Maps, even partial ones, of today's enormous Internet, whether of its physical wiring, its information content, or some other aspect, challenge both creator and user. Yet a map, even a complicated one, has a way of bounding chaos and giving us a ready-packaged mental construct. Some time ago, we discovered Martin Dodge's remarkable collection of Internet maps at the Centre for Advanced Spatial Analysis, University College London. His Atlas of Cyberspaces (<http://www.cybergeography.org/atlas/atlas.html>) contains separate collections for maps of:

- ISP and Internet backbone networks
- Three-dimensional information spaces
- Information landscapes or visualizations
- Cyberspace using geographic metaphors

The Atlas of Cyberspaces also includes examples of Web site maps and several other map categories.

Internet Message Access Protocol

Internet Message Access Protocol (IMAP) is a standard **protocol** for accessing **e-mail** from your local server. IMAP (the latest version is IMAP4) is a **client/server** protocol in which e-mail is received and held for you by your Internet server. You (or your e-mail client) can view just the heading and the sender of the letter and then decide whether to download the mail. You can also create and manipulate folders or mailboxes on the server, delete messages, or search for certain parts or an entire note. IMAP requires continual access to the server during the time that you are working with your mail.

A less sophisticated protocol is Post Office Protocol 3 (POP3). With POP3, your mail is saved for you in your mail box on the server. When you read your mail, all of it is immediately downloaded to your computer and, unless you request it, no longer maintained on the server.

IMAP can be thought of as a remote file server. POP can be thought of as a "store-and-forward" service.

POP and IMAP deal with the receiving of e-mail from your local server and are not to be confused with Simple Mail Transfer Protocol (SMTP), a protocol for transferring e-mail between points on the Internet. You send e-mail with SMTP and a mail handler receives it on your recipient's behalf. Then the mail is read using POP or IMAP.

Internet Open Trading Protocol

Internet Open Trading Protocol (IOTP) is a set of standards that makes all electronic purchase transactions consistent for customers, merchants, and other involved parties, regardless of payment system. IOTP accommodates a wide range of payment systems such as **Secure Electronic Transaction**, **digital cash**, e-checks, and debit cards. Payment system data is encapsulated within IOTP messages. IOTP is designed to handle a transaction that involves a number of different parties: the customer, merchant, credit checker and certifier, bank, and delivery handler. IOTP uses the Extensible Markup Language (XML) to define data that encompasses everything that may be needed in a transaction.

In the "real world," you can negotiate certain factors when considering a purchase. These include choosing who you conduct business with, whether it will be conducted in person or by phone, the method of payment, the provision of a payment receipt, and the delivery of the product. In the virtual world, IOTP is designed to ensure that all of these factors are successfully and securely performed.

Companies contributing to the development of IOTP include Hewlett Packard, IBM, JCP, MasterCard International, Smart Card Integrations, Sun Microsystems, and Wells Fargo Bank.

Internet problems

Here are:

- Three rules-of-thumb for dealing with Internet problems
- A table showing the most common codes and messages you're likely to see on your Web browser (HTTP), when accessing **Usenet**, using **e-mail**, or using the **FTP** protocol to upload or download files

A Table Showing the Most Common Codes and Messages

Error message	What it means	What you can do
400—Bad request	You entered a URL that is not accepted as correct. Possibly the server being contacted doesn't recognize the document you are asking for or it may no longer exist. It is also possible that it is correct but you aren't authorized to access it.	Check the URL to see if it's correctly spelled and that every letter is in the right (upper- or lower-) case. Check colons, numbers of slashes, and tildes.
401—Unauthorized	The site being accessed is protected and you either entered the incorrect password or the host does not want users coming from your domain to enter. Some sites will only allow specific domains to access the site. For example, some U.S. government sites (with the .gov top-level domain name) will only permit users coming from .gov or .edu (educational sites) to gain access. Or some educational sites only allow access from other educational sites.	If you are sure you have access to the site, try typing the password again. If you don't have a password or your domain does not have access to the site, you won't be able to access it.
403—Forbidden	You are not permitted to access this document. It is either password-protected or the host does not want your domain to enter.	See above.
404—Not found	The host server can't find the HTML document at the URL you've entered. Either you have mistyped the URL, the document no longer exists, or you've been given the wrong URL.	If your URL ends in ".htm", try ".html" (and vice versa). To find out whether the site hosting the document is still active, delete everything after the last slash in the URL. If this doesn't work, try deleting the slash and adding .htm or .html to the end. If the site is still running, try and find the page from another location on the site that you can reach.
550—xxxxxxxxx is not a known user	Using e-mail, you sent a note to an e-mail address that isn't recognized at the mail server you've specified. The e-mail note got all the way to the mail server (so that part's right), but you may have entered the user part of the e-mail address incorrectly or the user may no longer have an account on that server.	Make sure you entered the correct e-mail user name. If you suspect it's an old address or was mistyped in a note sent to you, try looking up a new address using the person's name. Try e-mail address finding tools .
Bad file request	The form you're trying to access is not supported by your browser or there is an error in the form.	Try using a different browser. If the problem persists or another browser is not available, send an e-mail note to the site's Webmaster.
Cannot add form submission result to bookmark list	This error message occurs when you've submitted a search request and then try to save the result as a bookmark. Even though it may look like a valid address, the resulting page does not have a URL that can be reused so it can't be added to your bookmark list.	Use the Save As command to save the page to your hard drive. Then you can open the saved HTML page in your browser and add that to your bookmark list.
Connection refused by host	You're not permitted to access this document either because it's password-protected or the host doesn't permit your domain to enter.	If you have access to the site and you know the password, try again, making sure you type it correctly and with the correct case.
Failed DNS lookup	The URL you requested could not be translated into a valid Internet address by the domain name system. This is either a result of a mistake in the system or you could have mistakenly entered an incorrect URL.	Mistakes in DNS lookups are a common occurrence. Simply clicking the Reload button may correct the error. If the error persists, you may have entered an incorrect host name. Try typing the URL again.
File contains no data	The site you accessed doesn't contain any Web pages on it. It's possible that you're trying to access the site while the page is being uploaded.	Try waiting a minute and clicking on the Reload button. Make sure that the URL is typed in correctly. If the problem persists, try again later.

#	Error message	What it means	What you can do
A	Helper application not found	You're trying to load a file of a type that your browser doesn't recognize. Most browsers can be enabled to view or load file types that they don't otherwise recognize. These files can be sound files, movie clips, graphics, ZIP archive files, or any other type of file you are trying to download.	The dialog box that carries this message will tell you the file type that is missing. You can then follow your browser's instructions for assigning a viewer for each file format you wish to view online. It's often better to have certain file formats not assigned to helper applications for Internet browsers. When files are not assigned to helper applications, the dialog box you receive has a "Save to Disk" option. This can often be useful when you want to download files, such as ZIP archive files, to save them instead of extracting them right away.
F	Host unavailable	The server computer that hosts this site could not be reached. The server may be offline or down for maintenance.	Try clicking on the Reload button. If it still doesn't work, try again later.
H	Host unknown	The server you're trying to reach is not connected, or you have lost your own connection. You may have also entered the URL incorrectly.	Click the Reload button and try again. Occasionally, packets don't arrive on the Internet and a second try will work. Next, make sure you are connected to the Internet. If you have lost your connection, simply reconnect and try the URL again. If you still receive the error, check the URL for typos and case-sensitivity.
I			
K	Network connection was refused by the server	Some servers have limits on the number of people or request they can handle at a time. If you get this message, the server is probably too busy to handle one more user. When the server doesn't create its own message to handle this error, this generic message is displayed instead.	Try clicking the Reload button until you connect. Or try again later.
M	NNTP server error	This error occurs when you are trying to log on to a Usenet newsgroup. An NNTP server is part of your Internet service provider's software, so if this error occurs the software may be malfunctioning or the newsgroup does not exist.	Make sure that the URL is typed correctly. If you still receive the error, wait a while and try again. If the problem still persists, contact your access provider and make them aware of the problem.
P	Permission denied	This error occurs when you are connected with an FTP site and you are either uploading or downloading. Sometimes the site administrator doesn't want you to upload to the site, download a certain file, or access a certain directory. The site may also be too busy.	Check that you are using the correct procedure to upload or download the file. Then keep trying until you succeed. If you still receive the error and know that you're able to upload or download to that site, contact the Webmaster by phone or e-mail.
R	Too many connections—try again later	The limit to the number of people who can use the site at one time has been exceeded. You'll have to wait your turn.	Keep clicking the Reload button until you connect or try again later when there is likely to be less traffic.
S	Too many users	To avoid slow uploading and downloading rates, site administrators set a maximum number of users that can access the site at one time. Your request is one too many.	Keep trying until you connect or try again later when there is less Internet traffic. Check to see whether the site has mirrors, and try one of those.
U	Unable to locate host	The server is either down for maintenance or you may have lost your connection.	Click the Reload button; sometimes there is an intermittent problem on the Internet. Then make sure you're connected to the Internet. If you have lost your connection, simply reconnect and try the URL again. If you still receive the error, check the URL for typos and case-sensitivity.
V,W			
X,Y,Z			

Error message	What it means	What you can do
Unable to locate the server	The server indicated in the URL you typed or clicked from either no longer exists or was entered incorrectly.	Check the URL to see if everything is correct. Make sure that everything is correctly spelled and in the correct case (some servers are case-sensitive). You can also check with the source of the URL to verify that it is correct.
Viewer not found	Your browser doesn't recognize files of this type. Most browsers can be extended to be able to view or load file types that are not otherwise recognized by browsers, such as movie or sound files.	When this dialog box appears, search for a helper application that will open files of this format. Then follow your browser's instructions for assigning this viewer to open files of that format online.
You can't log on as an anonymous user	This is another FTP error message. Most browsers submit "anonymous" as your user ID and your email address as your password. The FTP site you are connecting to may not allow "anonymous" access. This error will also occur when the FTP server is currently at its limit of "anonymous" users. Another possibility is that your browser doesn't support anonymous FTP access (for example, America Online's browser).	Keep trying to access the FTP site until you succeed. Sometimes the FTP server is too busy. However, if you don't have a browser that allows anonymous FTP access or the site is password-protected, your user ID and password manually using FTP software such as WS_FTP or CuteFTP.

Three Rules-of-Thumb for Dealing with Internet Problems

1. If you get a message saying the domain name server (DNS) can't find your page and you're sure you've typed it in correctly or clicked on a valid link, try it again—TWO more times! (Sometimes **packets** don't get there!)
2. If you get a "Not found" message, the page may be temporarily missing because of miscoding at the target site. Try it again tomorrow...or try the home page for the site and send e-mail asking them to restore the page.
3. Be aware that sometimes a page you've visited recently may be coming from your **cache** (or the cache on a **proxy** server within your company). To get the "fresh" version of the page, click on "Reload" in your tool bar.

Internet Protocol

The Internet Protocol (IP) is the method or **protocol** by which **data** is sent from one computer to another on the **Internet**. Each computer (known as a **host**) on the Internet has at least one **IP address** that uniquely identifies it from all other computers on the Internet. When you send or receive data (for example, an e-mail note or a Web page), the message gets divided into little chunks called packets. Each of these packets contains both the sender's Internet address and the receiver's address. Any **packet** is sent first to a **gateway** computer that understands a small part of the Internet. The gateway computer reads the destination address and forwards the packet to an adjacent gateway that in turn reads the destination address and so forth across the Internet until one gateway recognizes the packet as belonging to a computer within its immediate neighborhood or **domain**. That gateway then forwards the packet directly to the computer whose address is specified.

Because a message is divided into a number of packets, each packet can, if necessary, be sent by a different route across the Internet. Packets can arrive in a different order than the order they were sent in. The Internet Protocol just delivers them. It's up to another protocol, the Transmission Control Protocol (TCP) to put them back in the right order.

V,W

X,Y,Z

IP is a connectionless protocol, which means that there is no continuing connection between the end points that are communicating. Each packet that travels through the Internet is treated as an independent unit of data without any relation to any other unit of data. (The reason the packets do get put in the right order is because of TCP, the connection-oriented protocol that keeps track of the packet sequence in a message.) In the Open Systems Interconnection (OSI) communication model, IP is in **layer 3**, the Networking Layer.

The most widely used version of IP today is Internet Protocol Version 4 (IPv4). However, IP Version 6 (**IPv6**) is also beginning to be supported. IPv6 provides for much longer addresses and therefore for the possibility of many more Internet users and devices. IPv6 includes the capabilities of IPv4 and any server that can support IPv6 packets can also support IPv4 packets.

Internet Protocol Security

See "IPsec"

Internet Relay Chat

For terms frequently used in online keyboard chatting, see **chat abbreviations**.

Internet Relay Chat (IRC) is a system for **chatting** that involves a set of rules and conventions and **client/server** software. On the Web, certain sites such as Talk City or IRC networks such as the **Undernet** provide **servers** and help you download an IRC **client** to your PC. Talk City also offers an IRC client **applet** that it downloads for you as part of their home page so that you can start chatting right away.

You can start a chat group (called a **channel**) or join an existing one. There is a protocol for discovering existing chat groups and their members. Depending on the type of network, nicknames can be reserved (registered) or just used during the session. Some channels encourage you to register a nickname that you always use and even offer space for a personal profile, picture, and personal home page link.

Popular ongoing IRC channels are #hottub and #riskybus. A number of channels are set up and conducted in foreign languages. The most common IRC networks are IRCnet (mostly European), EFnet (mostly North American), Undernet, and Dalnet. Popular IRC clients include mIRC for Windows, IRClc for Mac OS, and irc2 (the original client) for UNIX-base operating systems.

The IRC protocol uses **Transmission Control Protocol** (you can IRC via a **Telnet** client), usually on **port 6667**.

Internet Research Task Force

The IRTF is an activity of the of the **Internet Society**. The Internet Research Task Force (IRTF) works on network technology.

You can find out more about the IRTF at the Internet Society's home page.

Internet Server Application Program Interface

See "ISAPI"

Internet service provider

See "ISP"

Internet Society

The Internet Society is an international non-profit organization that acts as a guide and conscience for the workings of the Internet. It was founded in 1992 and is based on Reston, Virginia. The Internet Society supports the Internet Architecture Board (**IAB**), which supervises technical and other issues. Among the IAB's activities is the Internet Engineering Task Force (**IETF**), which oversees the evolution of **TCP/IP**.

Internet time

Internet time is the concept that events occur at a faster rate on the Internet than elsewhere or that, everywhere, the Internet is affecting the pace of change. Andy Grove, CEO of Intel, is quoted as saying, "The world now runs on Internet time."

Internet traffic

Several major Internet **backbone** providers have Web sites that post hourly or more frequent statistics on how fast data is travelling on their backbone lines and the percentage of data **packet** that are being lost. Our table summarizes these sites, the information they provide, and how often they are updated.

This Internet traffic statistics site...	Gives you this information
AT&T Internet Network Status http://ipnetwork.bgtmo.ip.att.net/delay.html or http://ipnetwork.bgtmo.ip.att.net/loss.html	Backbone delay (latency) or packet loss between specified U.S. cities (both pages updated every 30 minutes)

This Internet traffic statistics site...	Gives you this information
Cable and Wireless Global Internet Backbone http://sla.cw.net	Backbone delay (latency) and packet loss by global region (updated every 10 minutes)
UUNET http://www.uunet.com/lang.en/customers/sla/latency.html	Monthly statistics for North America, Transatlantic, and Europe

Internet voting

See “e-voting”

Internet2

Internet2 is a collaboration among more than 100 U.S. universities to develop networking and advanced applications for learning and research. Since much teaching, learning, and collaborative research may require real-time multimedia and high-**bandwidth** interconnection, a major aspect of Internet2 is adding sufficient network infrastructure to support such applications. But Internet2 also intends to investigate and develop new ways to use the Internet and the Internet2 infrastructure for its educational purposes. Although Internet2 is not envisioned as a future replacement for the Internet, its organizers hope to share their developments with other networks, including the Internet. Internet2 will include and further develop the National Science Foundation’s very high-speed Backbone Network Service (vBNS) that currently interconnects research **supercomputer centers** in the U.S. The involved institutions plan to continue using the existing Internet for “ordinary” services such as e-mail, personal Web access, and newsgroups.

Internet2 collaborators plan to use Quality-of-Service (QoS) tools so that participants can reserve and use bandwidth for special events or in certain time periods. Here are some possibilities envisioned by Internet2:

Distributed learning modules: Conceptually, teachers and students can share materials in cyberspace with students learning in a self-directed manner under the supervision of an educational system or teacher. Internet2 foresees tools that would make it easy to create what they call LearningWare, using existing methodologies. Internet2 may also help realize the Instructional Management System (IMS), a standard process for using the Internet in developing and delivering learning packages and tracking outcomes. One can think of the IMS as a more structured way to exploit the potential learning materials on the World Wide Web.

New ways to envision and retrieve information: In the future, today’s text-oriented models of information structure could be replaced by interactive pictures of information structure (compare a textual taxonomy or table of contents with illustrations of interlinked and explodable animal forms, for example). With Internet2’s high-bandwidth connections, experiments in such information visualization will be possible; new ideas can be tried out. In environments where up-to-date information is valuable, information can be pushed to users at their request.

Virtual environment sharing: Sometimes called *tele-immersion*, participants in teleconferences could share the perception that everyone was in the same physical place, possibly with virtual (but somewhat real) models of shared work objects such as architectural models or multimedia storyboards. You would be able to see yourself with others in a far-away conference room, talking and perhaps manipulating objects in the room.

Virtual laboratory: A virtual laboratory would allow scientists in a number of different physical locations, each with unique expertise, computing resources, and/or data to collaborate efficiently not simply at a meeting but in an ongoing way. Effectively, such a project would extend and pool resources while engendering orderly communication and progress toward shared goals. For example, a group of astronomers and computer scientists at the supercomputing centers in the U.S. are attempting to share experiments and knowledge about the origin of the universe. Shared visualizations of alternative possibilities could conceivably suggest additional or refined alternatives. Virtual laboratories are also envisioned for the design and manufacturing of complex systems such as airplanes and for studying and forecasting weather patterns.

Internetwork Packet Exchange

See “IPX”

internetworking

Internetworking is a term used by Cisco, BBN, and other providers of network products and services as a comprehensive term for all the concepts, technologies, and generic devices that allow people and their computers to communicate across different kinds of **networks**. For example, someone at a computer on a **token ring** local area network may want to communicate with someone at a computer on an **Ethernet** local area network in another country using a **wide area network** interconnection. The common internetwork **protocols**, routing tables, and related network devices required to achieve this communication constitute internetworking.

The standard reference model for internetworking is Open Systems Interconnection (OSI), which could also be used as a model for intranetworking as well. OSI enables any technology to be related to another technology because each

can be related to the standard communication model. OSI provides a **layering** approach to the problem of exchanging data across a network or a network of networks so that the problem can be broken down into easier-to-understand components and so that boundaries between components can be more easily determined.

InterNIC

Until recently, InterNIC (Internet Network Information Center), a cooperative activity between the U.S. government and Network Solutions, Inc., was the organization responsible for registering and maintaining the **com**, **net**, and **org top-level domain** names on the World Wide Web. The actual registration was performed by Network Solutions, Inc. As a result of a new U. S. Government Statement of Policy (known as “the white paper”) in October 1998, competition will be introduced in domain name registration for these top-level domains and a new, non-profit global organization, the Internet Corporation of Assigned Names and Numbers (**ICANN**), has been designated to conduct the registrar accreditation process. ICANN has initially designated five new registrar companies—in addition to Network Solutions—for a two-month test period. After that period, additional registrars are expected to be accredited.

In addition to the **com**, **net**, and **org** domain name, geographically identified domains in the U.S. such as those for cities and towns are administered by US Domain Name Registration Services. There are also registries for Canada, Mexico, Europe, Asia Pacific countries, and other countries.

interoperability

Interoperability (pronounced IHN-tuhr-AHP-uhr-uh-BIHL-ih-tee) is the ability of a system or a product to work with other systems or products without special effort on the part of the customer. Interoperability becomes a quality of increasing importance for information technology products as the concept that “The network is the computer” becomes a reality. For this reason, the term is widely used in product marketing descriptions.

Products achieve interoperability with other products using either or both of two approaches:

- By adhering to published **interface** standards
- By making use of a “broker” of services that can convert one product’s interface into another product’s interface “on the fly”

A good example of the first approach is the set of standards that have been developed for the World Wide Web. These standards include **TCP/IP**, **Hypertext Transfer Protocol**, and **HTML**. The second kind of interoperability approach is exemplified by the Common Object Request Broker Architecture (**CORBA**) and its Object Request Broker (**ORB**).

Compatibility is a related term. A product is compatible with a standard but interoperable with other products that meet the same standard (or achieve interoperability through a broker).

interpreted

An interpreted program, sometimes called a *script*, is a program whose instructions are actually a logically sequenced series of operating system commands, handled one at a time by a **command interpreter**. In turn, the command interpreter requests services from the operating system. The writer of the interpreted program need not be concerned by low-level storage management considerations. On the other hand, an interpreted program can not be as efficient as a *compiled* program, which has been processed by a language compiler. A language compiler converts source statements into something close to the strings of 0’s and 1’s that a processor ultimately is given to work on. Because this work is already done before a compiled program is run, it runs much more quickly.

An interpreted program in a language such as **Perl** is much easier to write than a program written for a compiler. Interpreted programs are ideal for small tasks and for “gluing together” a succession of compiled programs that are run from the interpreted program.

interprocess communication

Interprocess communication (IPC) is a set of programming **interfaces** that allow a programmer to create and manage individual program **processes** that can run concurrently in an **operating system**. This allows a program to handle many user requests at the same time. Since even a single user request may result in multiple processes running in the operating system on the user’s behalf, the processes need to communicate with each other. The IPC interfaces make this possible. Each IPC method has its own advantages and limitations so it is not unusual for a single program to use all of the IPC methods. IPC methods include:

- **Pipes** and **named pipes**
- **Message queueing**
- **Semaphores**
- **Shared memory**
- **Sockets**

interrupt

An interrupt is a signal from a device attached to a computer or from a program within the computer that causes the main program that operates the computer (the *operating system*) to stop and figure out what to do next. Almost all personal (or larger) computers today are *interrupt-driven*—that is, they start down the list of computer instructions in one program (perhaps an application such as a word processor) and keep running the instructions until either (A) they can’t go any

further or (B) an interrupt signal is sensed. After the interrupt signal is sensed, the computer either resumes running the program it was running or begins running another program.

Basically, a single computer can perform only one computer instruction at a time. But, because it can be interrupted, it can take turns in which programs or sets of instructions that it performs. This is known as *multitasking*. It allows the user to do a number of different things at the same time. The computer simply takes turns managing the programs that the user effectively starts. Of course, the computer operates at speeds that make it seem as though all of the user's tasks are being performed at the same time. (The computer's operating system is good at using little pauses in operations and user think time to work on other programs.)

An operating system usually has some code that is called an *interrupt handler*. The interrupt handler prioritizes the interrupts and saves them in a *queue* if more than one is waiting to be handled. The operating system has another little program, sometimes called a *scheduler*, that figures out which program to give control to next.

In general, there are hardware interrupts and software interrupts. A hardware interrupt occurs, for example, when an I/O operation is completed such as reading some data into the computer from a tape drive. A software interrupt occurs when an application program terminates or requests certain services from the operating system. In a personal computer, a hardware interrupt request (**IRQ**) has a value associated with it that associates it with a particular device.

interrupt request

See "IRQ"

interstitial

An interstitial (something "in between") is a page that is inserted in the normal flow of editorial content structure on a Web site for the purpose of advertising or promotion. It can be more or less intrusive and the reaction of viewers usually depends on how welcome or entertaining the message is. An interstitial is usually designed to move automatically to the page the user requested after allowing enough time for the message to register or the ad(s) to be read.

intrabody signaling

See "personal area network"

intranet

An intranet is a private **network** that is contained within an **enterprise**. It may consist of many interlinked **local area networks** and also use leased lines in the **wide area network**. Typically, an intranet includes connections through one or more **gateway** computers to the outside

Internet. The main purpose of an intranet is to share company information and computing resources among employees. An intranet can also be used to facilitate working in groups and for teleconferences.

An intranet uses **TCP/IP**, **HTTP**, and other Internet protocols and in general looks like a private version of the Internet. With **tunneling**, companies can send private messages through the public network, using the public network with special encryption/decryption and other security safeguards to connect one part of their intranet to another.

Typically, larger enterprises allow users within their intranet to access the public Internet through **firewall** servers that have the ability to screen messages in both directions so that company security is maintained. When part of an intranet is made accessible to customers, partners, suppliers, or others outside the company, that part becomes part of an **extranet**.

intrusion detection

Intrusion detection (ID) is a type of security management system for computers and networks. An ID system gathers and analyzes information from various areas within a computer or a network to identify possible security breaches, which include both intrusions (attacks from outside the organization) and misuse (attacks from within the organization). ID uses *vulnerability assessment* (sometimes referred to as *scanning*), which is a technology developed to assess the security of a computer system or network.

Intrusion detection functions include:

- Monitoring and analyzing both user and system activities
- Analyzing system configurations and vulnerabilities
- Assessing system and file integrity
- Ability to recognize patterns typical of attacks
- Analysis of abnormal activity patterns
- Tracking user policy violations

ID systems are being developed in response to the increasing number of attacks on major sites and networks, including those of the Pentagon, the White House, NATO, and the U.S. Defense Department. The safeguarding of security is becoming increasingly difficult, because the possible technologies of attack are becoming ever more sophisticated; at the same time, less technical ability is required for the novice attacker, because proven past methods are easily accessed through the Web.

Typically, an ID system follows a two-step process. The first procedures are host-based and are considered the *passive* component, these include: inspection of the system's configuration files to detect inadvisable settings; inspection of the password files to detect inadvisable passwords; and inspection of other system areas to detect policy violations. The second procedures are network-based and are

considered the *active* component: mechanisms are set in place to reenact known methods of attack and to record system responses.

In 1998, ICSA.net, a leading security assurance organization, formed the Intrusion Detection Systems Consortium (IDSC) as an open forum for ID product developers with the aim of disseminating information to the end user and developing industry standards.

inverse multiplexing

Inverse multiplexing speeds up data transmission by dividing a data stream into multiple concurrent streams that are transmitted at the same time across separate channels (such as a T-1 or E-1 lines) and are then reconstructed at the other end back into the original data stream. Just the reverse of ordinary **multiplexing**, which combines multiple signals into a single signal, inverse multiplexing is a technique commonly used where data in a high-speed local area network (LAN) flows back and forth into a wide area network (WAN) across the "bottleneck" of a slower line such as a T-1 (1.544 Mbps). By using multiple T-1 lines, the data stream can be load-balanced across all of the lines at the same time. As a general rule, inverse multiplexing across up to 8 T-1 lines (or E-1 lines in Europe and elsewhere) is said to be less expensive than the cost of renting a T-3 (45 Mbps) line (or E-3 line in Europe and elsewhere).

Inverse multiplexing is also sometimes used in combination with **frame relay** and asynchronous transfer mode (ATM) transmission.

Inverse multiplexing is sometimes called *inverse muxing* or *imuxing*.

inverse-square law

The inverse-square law is a principle that expresses the way radiant energy propagates through space. The rule states that the power intensity per unit area from a point source, if the rays strike the surface at a right angle, varies inversely according to the square of the distance from the source.

Imagine a 40-watt lamp at the center of a spherical enclosure. The total **power** striking the surface of the sphere is 40 watts, no matter what the size of the sphere. Some people find this counter-intuitive, but it becomes obvious when we consider that all the radiated power (no more and no less) from the source must strike an enclosure of any size that completely surrounds the source. Thus, the power striking the interior of a sphere 10 meters across is the same (40 watts in this hypothetical example) as the power striking the interior of a sphere 100 meters across, 100 kilometers across, or 100,000 kilometers across. The power per unit area, however, does depend on the size of the sphere.

The surface area A (in meters squared) of a sphere having radius r (in meters) is given by:

$$A = (4 \pi) r^2$$

where π is the ratio of a sphere's circumference to its diameter, and is approximately equal to 3.14159. If the radius of a sphere is multiplied by some factor n , then the surface area increases by a factor of n^2 . This decreases the power per unit area by a factor of n^2 . Another way of saying this is that the power per unit area becomes n^{-2} times as great.

Increasing the diameter of a sphere from 10 to 100 meters makes it 10 times as large in diameter, and gives it 100 times the surface area. This cuts the light power per unit area from a lamp at the sphere's center by a factor of 100. The power landing on, say, one square centimeter of the sphere's interior becomes 1/100, or 0.01 times, as great, if the sphere's diameter grows from 10 to 100 meters. The law applies only as long as the point source is at the center of the sphere, so the rays from the source strike the sphere's surface at right angles.

Also see **meter**, **square meter**, and International System of Units (SI).

I/O

I/O (input/output), pronounced "eye-oh," describes any operation, program, or device that transfers data to or from a computer. Typical I/O devices are printers, hard disks, keyboards, and mice. In fact, some devices are basically input-only devices (keyboards and mice); others are primarily output-only devices (printers); and others provide both input and output of data (hard disks, diskettes, writable CD-ROMs).

IO.SYS

In the **Windows 95 operating system**, IO.SYS is an **executable binary file** (in other words, a program) that, when the operating system is **booted** (started), processes **instructions** that tell the operating system how the computer is set up. In Windows 95, IO.SYS replaced the older **MS-DOS** system files, IO.SYS and MSDOS.SYS. The newer IO.SYS contains all the information needed to start your computer and eliminates the need for the **CONFIG.SYS** and **autoexec.bat** files because the values in CONFIG.SYS and AUTOEXEC.BAT are in IO.SYS instead. Both of these files still come with Windows for older applications and drivers that need them.

In computers using DOS or Windows 3.x, the IO.SYS is loaded with the MSDOS.SYS file when the computer is booted. MSDOS.SYS is a text file that determines whether DOS or Windows is loaded. Because IO.SYS is a sequence of executable code rather than readable text, it is not editable like MSDOS.SYS, CONFIG.SYS, and AUTOEXEC.BAT.

To change **default** values that come with IO.SYS, you must change the CONFIG.SYS file. In loading IO.SYS, the system picks up any changed values that are present in the CONFIG.SYS file.

IOS

IOS (Input/Output Supervisor) is a Microsoft Windows program that supervises the interaction between **file system** requests and events and **input/output** device **drivers**.

IP

See “Internet Protocol”

IP address

This definition is based on Internet Protocol Version 4. See Internet Protocol Version 6 (**IPv6**) for a description of the newer 128-bit IP address. Note that the system of IP address classes described here, while forming the basis for IP address assignment, is generally bypassed today by use of Classless Inter-Domain Routing (**CIDR**) addressing.

In the most widely installed level of the Internet Protocol (**IP**) today, an IP address is a 32-bit number that identifies each sender or receiver of information that is sent in **packets** across the Internet. When you request an HTML page or send e-mail, the Internet Protocol part of **TCP/IP** includes your IP address in the message (actually, in each of the packets if more than one is required) and sends it to the IP address that is obtained by looking up the **domain name** in the **Uniform Resource Locator** you requested or in the e-mail address you’re sending a note to. At the other end, the recipient can see the IP address of the Web page requestor or the e-mail sender and can respond by sending another message using the IP address it received.

An IP address has two parts: the identifier of a particular network on the Internet and an identifier of the particular device (which can be a server or a workstation) within that network. On the Internet itself—that is, between the **router** that move packets from one point to another along the route—only the network part of the address is looked at.

The Network Part of the IP Address

The Internet is really the interconnection of many individual networks (it’s sometimes referred to as an *internetwork*). So the Internet Protocol (**IP**) is basically the set of rules for one network communicating with any other (or occasionally, for broadcast messages, all other networks). Each network must know its own address on the Internet and that of any other networks with which it communicates. To be part of the Internet, an organization needs an Internet network number, which it can request from the Network Information Center (NIC). This unique network number is included in any packet sent out of the network onto the Internet.

The Local or Host Part of the IP Address

In addition to the network address or number, information is needed about which specific machine or host in a network is sending or receiving a message. So the IP address needs both

the unique network number and a host number (which is unique within the network). (The host number is sometimes called a *local* or *machine address*.)

Part of the local address can identify a subnetwork or **subnet** address, which makes it easier for a network that is divided into several physical subnetworks (for example, several different local area networks) to handle many devices.

IP Address Classes and Their Formats

Since networks vary in size, there are four different address formats or classes to consider when applying to NIC for a network number:

- **Class A** addresses are for large networks with many devices.
- **Class B** addresses are for medium-sized networks.
- **Class C** addresses are for small networks (fewer than 256 devices).
- **Class D** addresses are multicast addresses.

The first few bits of each IP address indicate which of the address class formats it is using. The address structures look like this:

Class A	0	Network (7 bits)	Local address (24 bits)
Class B	10	Network (14 bits)	Local address (16 bits)
Class C	110	Network (21 bits)	Local address (8 bits)
Class D	1110	Multicast address (28 bits)	

The IP address is usually expressed as four decimal numbers, each representing eight bits, separated by periods. This is sometimes known as the **dot address** and, more technically, as *dotted quad notation*. For Class A IP addresses, the numbers would represent “network.local.local.local”; for a Class C IP address, they would represent “network.network.network.local”. The number version of the IP address can (and usually is) represented by a name or series of names called the **domain name**.

The Internet’s explosive growth makes it likely that, without some new architecture, the number of possible network addresses using the scheme above would soon be used up (at least, for Class C network addresses). However, a new IP version, **IPv6**, expands the size of the IP address to 128 bits, which will accommodate a large growth in the number of network addresses. For hosts still using IPv4, the use of **subnets** in the host or local part of the IP address will help reduce new applications for network numbers. In addition, most sites on today’s mostly IPv4 Internet have gotten around the Class C network address limitation by using the Classless Inter-Domain Routing (**CIDR**) scheme for address notation.

Relationship of the IP Address to the Physical Address

The machine or physical address used within an organization's local area networks may be different than the Internet's IP address. The most typical example is the 48-bit **Ethernet** address. TCP/IP includes a facility called the Address Resolution Protocol (**ARP**) that lets the administrator create a table that maps IP addresses to physical addresses. The table is known as the *ARP cache*.

Static versus Dynamic IP Addresses

The discussion above assumes that IP addresses are assigned on a static basis. In fact, many IP addresses are assigned dynamically from a pool. Many corporate networks and online services economize on the number of IP addresses they use by sharing a pool of IP addresses among a large number of users. If you're an America Online user, for example, your IP address will vary from one logon session to the next because AOL is assigning it to you from a pool that is much smaller than AOL's base of subscribers.

IP telephony

IP telephony (**Internet Protocol** telephony) is a general term for the technologies that use the Internet Protocol's **packet-switched** connections to exchange voice, fax, and other forms of information that have traditionally been carried over the dedicated circuit-switched connections of the public switched telephone network (**PSTN**). Using the Internet, calls travel as packets of data on shared lines, avoiding the tolls of the PSTN. The challenge in IP telephony is to deliver the voice, fax, or video packets in a dependable flow to the user. Much of IP telephony focuses on that challenge.

IP telephony service providers include or soon will include local telephone companies, long distance providers such as AT&T, cable TV companies, Internet service providers (**ISPs**), and fixed service **wireless** operators. IP telephony services also affect vendors of traditional **handheld** devices.

Currently, unlike traditional phone service, IP telephony service is relatively unregulated by government. In the U.S., the Federal Communications Commission (FCC) regulates phone-to-phone connections, but says they do not plan to regulate connections between a phone user and an IP telephony service provider.

VoIP is an organized effort to standardize IP telephony. IP telephony is an important part of the **convergence** of computers, telephones, and television into a single integrated information environment. Also see another general term, computer-telephony integration (**CTI**), which describes technologies for using computers to manage telephone calls.

IPC

See "interprocess communication"

IPI

IPI (Intelligent Peripheral Interface) is a high-**bandwidth** interface between a computer and a **hard disk** or a tape device. Devices using IPI can transfer data between the hard drive and **RAM** in the range between 3 and 25 **megabytes** per second.

The latest version of IPI is IPI-3, which supports **redundant array of independent disks**. The official IPI standards are:

- ANSI/ISO 9318-3 Intelligent Peripheral Interface—
Device Generic Command Set for Magnetic and Optical Disk Drives
- ANSI/ISO 9318-4 Intelligent Peripheral Interface—
Device Generic Command Set for Magnetic Tape Drives

IPL

IPL (initial program load) is a **mainframe** term for the loading of the **operating system** into the computer's main **memory**. A mainframe operating system (such as OS/390) contains many megabytes of code that is customized by each installation, requiring some time to load the code into the memory. On a personal computer, **booting** or re-booting (re-starting) is the equivalent to IPLing (the term is also used as a verb).

In earlier operating systems, when you added devices to the hardware system, you had to stop the system, change the configuration file, and then "re-IPL," an activity that meant the system would be unavailable for some period of time. Today's systems provide dynamic reconfiguration so that the system can keep running.

IPng

See "IPv6"

IPO

See "IPO"

IPP

An Internet presence provider (IPP) is a company that provides the disk space, high-speed Internet connection, and possibly the **Web site** design and other services for companies, organizations, or individuals to have a visible **presence** (meaning Web site) on the Internet. Using an IPP means that the owner of the Web site doesn't need to have the files for it served from the owner's computer. Although one can maintain a Web site from a smaller computer if site traffic is very low, most moderate- to high-traffic Web sites require a relatively expensive, higher-speed connection to the Internet. For this reason alone, most individuals and organizations put their sites on a server at an Internet presence provider.

Many Internet service providers (**ISPs**) act as both Internet access provider (IAP) and Internet presence provider, although some provide only one or the other service. An IPP sometimes offers design and production services for a Web site as a package or on a consulting basis. Some Internet presence providers use the term *hosting* or **virtual hosting** for the “housing and maintenance” aspects of presence providing. Typical service packages at different prices include assistance with **domain name** registration, a specific amount of hard disk space for Web pages, a number of e-mail addresses, the arrangement of server application or database access from Web pages, **e-commerce** shopping page setup, a specific amount of allowable Web data traffic, and assistance in setting up and maintaining the site.

Some presence providers let you put your own server machine (or lease one to you) at their location and they manage it for you. This is called *co-location*.

IPPP

An IPPP (Internet presence provider and promoter) is a company that helps an enterprise create a **Web site**, arrange for **hosting** (housing, maintaining, and providing Internet access) for the Web site, and promote an audience for it. Many Internet service providers (**ISPs**) are also IPPPs, but some ISPs simply offer users **access** to the Internet.

IPsec

IPsec (Internet Protocol Security) is a developing standard for security at the network or **packet** processing layer of network communication. Earlier security approaches have inserted security at the **Application** layer of the communications model. IPsec will be especially useful for implementing **virtual private networks** and for remote user access through dial-up connection to private networks. A big advantage of IPsec is that security arrangements can be handled without requiring changes to individual user computers. Cisco has been a leader in proposing IPsec as a standard (or combination of standards and technologies) and has included support for it in its network **routers**.

IPsec provides two choices of security service: Authentication Header (AH), which essentially allows authentication of the sender of data, and Encapsulating Security Payload (ESP), which supports both authentication of the sender and encryption of data as well. The specific information associated with each of these services is inserted into the packet in a header that follows the IP packet header. Separate key protocols can be selected, such as the ISAKMP/Oakley protocol.

Officially spelled IPsec by the IETF, the term often appears as IPSec and IPSEC.

IPv6

IPv6 (Internet Protocol Version 6) is the latest level of the Internet Protocol (**IP**) and is now included as part of IP support in many products including the major computer **operating systems**. IPv6 has also been called “IPng” (IP Next Generation). Formally, IPv6 is a set of specifications from the Internet Engineering Task Force (**IETF**). IPv6 was designed as an evolutionary set of improvements to the current IP Version 4. Network **hosts** and intermediate **nodes** with either IPv4 or IPv6 can handle **packets** formatted for either level of the Internet Protocol. Users and service providers can update to IPv6 independently without having to coordinate with each other.

The most obvious improvement in IPv6 over the IPv4 is that **IP addresses** are lengthened from 32 bits to 128 bits. This extension anticipates considerable future growth of the Internet and provides relief for what was perceived as an impending shortage of network addresses.

IPv6 describes rules for three types of addressing: **unicast** (one host to one other host), **anycast** (one host to the nearest of multiple hosts), and **multicast** (one host to multiple hosts). Additional advantages of IPv6 are:

- Options are specified in an extension to the header that is examined only at the destination, thus speeding up overall network performance.
- The introduction of an “anycast” address provides the possibility of sending a message to the nearest of several possible gateway hosts with the idea that any one of them can manage the forwarding of the packet to others. Anycast messages can be used to update routing tables along the line.
- Packets can be identified as belonging to a particular “flow” so that packets that are part of a multimedia presentation that needs to arrive in “real time” can be provided a higher quality-of-service relative to other customers.
- The IPv6 header now includes extensions that allow a packet to specify a mechanism for authenticating its origin, for ensuring data integrity, and for ensuring privacy.

IPX

IPX (Internetwork Packet Exchange) is a networking **protocol** from Novell that interconnects networks that use Novell’s **NetWare** clients and servers. IPX is a datagram or **packet** protocol. IPX works at the Network layer of communication protocols and is connectionless (that is, it doesn’t require that a connection be maintained during an exchange of packets as, for example, a regular voice phone call does).

Packet acknowledgment is managed by another Novell protocol, the Sequenced Packet Exchange (SPX). Other related Novell NetWare protocols are: the Routing Information Protocol (RIP), the Service Advertising Protocol (SAP), and the NetWare Link Services Protocol (NLSP).

IR

See "infrared radiation"

IRC

See "Internet Relay Chat"

IRQ

An IRQ (**interrupt request**) value is an assigned location where the computer can expect a particular device to interrupt it when the device sends the computer signals about its operation. For example, when a printer has finished printing, it sends an **interrupt** signal to the computer. The signal momentarily interrupts the computer so that it can decide what processing to do next. Since multiple signals to the computer on the same interrupt line might not be understood by the computer, a unique value must be specified for each device and its path to the computer. Prior to Plug-and Play (PnP) devices, users often had to set IRQ values manually (or be aware of them) when adding a new device to a computer.

If you add a device that does not support Pnp, the manufacturer will hopefully provide explicit directions on how to assign IRQ values for it. If you don't know what IRQ value to specify, you'll probably save time by calling the technical support phone number for the device manufacturer and asking.

irrational number

An irrational number is a **real number** that cannot be reduced to any ratio between an **integer** p and a **natural number** q . The union of the set of irrational numbers and the set of **rational numbers** forms the set of real numbers. In mathematical expressions, unknown or unspecified irrationals are usually represented by u through z . Irrational numbers are primarily of interest to theoreticians. Abstract mathematics has potentially far-reaching applications in communications and computer science, especially in data encryption and security.

Examples of irrational numbers are $2^{1/2}$ (the square root of 2), $3^{1/3}$ (the cube root of 3), the circular ratio **pi**, and the natural **logarithm** base e . The quantities $2^{1/2}$ and $3^{1/3}$ are examples of **algebraic numbers**. Pi and e are examples of special irrationals known as a **transcendental numbers**. The decimal expansion of an irrational number is always nonterminating (it never ends) and nonrepeating (the digits display no repetitive pattern).

If x and z are irrationals such that $x < z$, then there always exists an irrational y such that $x < y < z$. The set of irrationals is "dense" like the set **Q** of rationals. But theoretically, the set of irrationals is "more dense." Unlike **Q**, the set of irrationals is *nondenumerable*. There are more nonterminating, nonrepeating decimals than is possible to list, even by implication. To prove this, suppose there is an implied list of all the nonterminating, nonrepeating decimal numbers between 0 and 1. Every such number consists of a zero followed by a decimal point, followed by an infinite sequence of digits from the set {0, 1, 2, 3, 4, 5, 6, 7, 8, 9}. Suppose the elements of the list are denoted x_1, x_2, x_3, \dots and the digits in the numbers are denoted a_{ij} . The list can be written like this:

$$\begin{aligned} x_1 &= 0.a_{11}a_{12}a_{13}a_{14}a_{15}a_{16} \dots \\ x_2 &= 0.a_{21}a_{22}a_{23}a_{24}a_{25}a_{26} \dots \\ x_3 &= 0.a_{31}a_{32}a_{33}a_{34}a_{35}a_{36} \dots \\ x_4 &= 0.a_{41}a_{42}a_{43}a_{44}a_{45}a_{46} \dots \\ x_5 &= 0.a_{51}a_{52}a_{53}a_{54}a_{55}a_{56} \dots \\ x_6 &= 0.a_{61}a_{62}a_{63}a_{64}a_{65}a_{66} \dots \\ &\dots \end{aligned}$$

Even though we don't know the actual values of any of the digits, it is easy to imagine a number between 0 and 1 that can't be in this list. Think of a number y of the following form:

$$y = 0.b_{11}b_{22}b_{33}b_{44}b_{55}b_{66} \dots$$

such that no b_{ii} in y is equal to the corresponding a_{ii} in the list. The resulting number y is nonterminating and nonrepeating, is between 0 and 1, but is not equal to any x_i in the list, because there is always at least one digit that does not match.

The non-denumerability of the set of irrational numbers has far-reaching implications. Perhaps most bizarre is the notion that "not all infinities are created equal." Although the set of rationals and the set of irrationals are both infinite, the set of irrationals is larger in a demonstrable way.

IRTF

See "Internet Research Task Force"

IRU

See "Indefeasible Right of Use"

IS

1) IS (information system) is the collection of technical and human resources that provide the storage, computing, distribution, and communication for the information required by all or some part of an **enterprise**. A special form of IS is a management information system (**MIS**), which provides information for managing an enterprise.

2) IS (information services) is a common name for an organization within an enterprise that is responsible for its data processing and information system or systems.

ISA

See “ISA”

ISAM

ISAM (Indexed Sequential Access Method) is a file management system developed at IBM that allows **records** to be accessed either sequentially (in the order they were entered) or randomly (with an index). Each index defines a different ordering of the records. An employee database may have several indexes, based on the information being sought. For example, a name index may order employees alphabetically by last name, while a department index may order employees by their department. A key is specified in each index. For an alphabetical index of employee names, the last name field would be the key.

ISAM was developed prior to **VSAM** (Virtual Storage Access Method) and relational databases.

ISAPI

ISAPI (Internet Server Application Program Interface) is a set of Windows program calls that let you write a Web server application that will run faster than a common gateway interface (CGI) application. A disadvantage of a CGI application (or “executable file,” as it is sometimes called) is that each time it is run, it runs as a separate process with its own address space, resulting in extra instructions that have to be performed, especially if many instances of it are running on behalf of users. Using ISAPI, you create a dynamic link library (DLL) application file that can run as part of the Hypertext Transport Protocol (HTTP) application’s process and address space. The DLL files are loaded into the computer when HTTP is started and remain there as long as they are needed; they don’t have to be located and read into storage as frequently as a CGI application.

Existing CGI applications can be converted into ISAPI application DLLs without having to rewrite their logic. However, they do need to be written to be **thread-safe** so that a single instance of the DLL can serve multiple users.

A special kind of ISAPI DLL is called an ISAPI **filter**, which can be designated to receive control for every HTTP request. You can create an ISAPI filter for **encryption** or decryption, for logging, for request screening, or for other purposes.

ISBN

The ISBN (International Standard Book Number) is a unique number assigned to a book title by its publisher for tracking and ordering purposes. An example is:

ISBN 0-385-49531-5

which is the ISBN for Simon Singh’s *The Code Book*, a book about cryptography.

Publishers, retailers, libraries, and readers use the ISBN as a way to specify a particular book without confusion.

The principles and procedures for international standard book numbering are contained in the International Organization for Standardization’s Recommendation 2108.

iSCSI

iSCSI is Internet SCSI (Small Computer System Interface), a new Internet Protocol (IP)-based storage networking standard for linking data storage facilities, developed by the Internet Engineering Task Force (IETF). By carrying **SCSI** commands over IP networks, iSCSI is used to facilitate data transfers over intranets and to manage storage over long distances. The iSCSI **protocol** is among the key technologies expected to help bring about rapid development of the storage area network (SAN) market, by increasing the capabilities and performance of storage data transmission. Because of the ubiquity of IP networks, iSCSI can be used to transmit data over local area networks (LANs), wide area networks (WANs), or the Internet and can enable location-independent data storage and retrieval.

How iSCSI Works:

When an end user or application sends a request, the **operating system** generates the appropriate SCSI commands and data request, which then go through **encapsulation** and, if necessary, **encryption** procedures. A **packet header** is added before the resulting IP packets are transmitted over an **Ethernet** connection. When a packet is received, it is decrypted (if it was encrypted before transmission), and disassembled, separating the SCSI commands and request. The SCSI commands are sent on to the SCSI controller, and from there to the SCSI storage device. Because iSCSI is bi-directional, the protocol can also be used to return data in response to the original request.

iSCSI is one of two main approaches to storage data transmission over IP networks; the other method, Fibre Channel over IP (**FC/IP**), translates **Fibre Channel** control codes and data into IP packets for transmission between geographically distant Fibre Channel SANs. FC/IP (also known as *Fibre Channel tunneling* or *storage tunneling*) can only be used in conjunction with Fibre Channel technology; in comparison, iSCSI can run over existing Ethernet networks. A number of vendors, including Cisco, IBM, and Nishan have introduced iSCSI-based products (such as **switches** and **routers**). Both iSCSI and FC/IP are proposed standards, and are expected to be ratified by the end of 2001.

ISDN

ISDN (Integrated Services Digital Network) is a set of **CCITT/ITU** standards for digital transmission over ordinary telephone copper wire as well as over other media. Home and business users who install an ISDN **adapter** (in place of a **modem**) can see highly-graphic Web pages arriving very

quickly (up to 128 **Kbps**). ISDN requires adapters at both ends of the transmission so your access provider also needs an ISDN adapter. ISDN is generally available from your phone company in most urban areas in the United States and Europe.

There are two levels of service: The Basic Rate Interface (**BRI**), intended for the home and small enterprise, and the Primary Rate Interface (**PRI**), for larger users. Both rates include a number of B-channels and a D-channel. Each **B-channel** carries data, voice, and other services. Each **D-channel** carries control and signaling information.

The Basic Rate Interface consists of two 64 Kbps B-channels and one 16 Kbps D-channel. Thus, a Basic Rate user can have up to 128 Kbps service. The Primary Rate consists of 23 B-channels and one 64 Kbps D-channel in the U.S. or 30 B-channels and 1 D-channel in Europe.

Integrated Services Digital Network in concept is the integration of both analog or voice data together with digital data over the same network. Although the ISDN you can install is integrating these on a medium designed for analog transmission, **broadband** ISDN (**BISDN**) will extend the integration of both services throughout the rest of the end-to-end path using fiber optic and radio media. Broadband ISDN will encompass **frame relay** service for high-speed data that can be sent in large bursts, the Fiber Distributed-Data Interface (**FDDI**), and the Synchronous Optical Network (**SONET**). BISDN will support transmission from 2 Mbps up to much higher, but as yet unspecified, rates.

IS-IS

One of the most commonly used **routing protocols**, the Intermediate System-to-Intermediate System protocol (IS-IS) is based on a routing method known as *DECnet Phase V* routing, in which routers known as *intermediate systems* exchange data about routing using a single **metric** to determine the network **topology**. IS-IS was developed by the International Organization for Standardization (**ISO**) as part of their Open Systems Interconnection (**OSI**) model. The first versions of IS-IS were used to manage routing within ISO Connectionless Network Protocol (CLNP) networks. IS-IS was ratified as a standard in 1990 (OSI IS-IS Intra-domain Routing Protocol, **IETF RFC 1142** [2], **ISO/IEC 10589** [3]).

In the OSI context, an *intermediate system* refers to a router, as opposed to an *end system* (ES), which refers to a **node**. ES-IS protocols allow routers and nodes to identify each other; IS-IS performs the same service between nodes for routing purposes. In common with other routing protocols such as **OSPF** (Open Shortest Path First), IS-IS is a *link state* protocol: it stores information about the state of links and uses that data to select paths. IS-IS is used to intermittently send out link state information across the network, so that each router can maintain a current picture of network topology. Optional metrics can be used to identify network delay, expense, and error involved with the use of a particular link.

ISO

ISO (International Organization for Standardization), founded in 1947, is a worldwide federation of national standards bodies from some 100 countries, one from each country. Among the standards it fosters is Open Systems Interconnection (**OSI**), a universal reference model for communication protocols. Many countries have national standards organizations such as the American National Standards Institute (**ANSI**) that participate in and contribute to ISO standards making.

"ISO" is not an abbreviation. It is a word, derived from the Greek *isos*, meaning "equal," which is the root for the prefix "iso-" that occurs in a host of terms, such as "isometric" (of equal measure or dimensions) and "isonomy" (equality of laws, or of people before the law). The name ISO is used around the world to denote the organization, thus avoiding the assortment of abbreviations that would result from the translation of "International Organization for Standardization" into the different national languages of members. Whatever the country, the short form of the Organization's name is always ISO.

ISO 14000 and 14001

ISO 14000 is a series of environmental management standards developed and published by the International Organization for Standardization (**ISO**) for organizations. The ISO 14000 standards provide a guideline or framework for organizations that need to systematize and improve their environmental management efforts. The ISO 14000 standards are not designed to aid the enforcement of environmental laws and do not regulate the environmental activities of organizations. Adherence to these standards is voluntary.

The ISO 14001 standard is the most important standard within the ISO 14000 series. ISO 14001 specifies the requirements of an environmental management system (EMS) for small to large organizations. An EMS is a systemic approach to handling environmental issues within an organization. The ISO 14001 standard is based on the Plan-Check-Do-Review-Improve cycle.

The Plan cycle deals with the beginning stages of an organization becoming ISO 14001-compliant. The Check cycle deals with checking and correcting errors. The Do cycle is the implementation and operation of the ISO 14001 standard within an organization. The Review cycle is a review of the entire process by the organization's top management. And the Improve cycle is a cycle that never ends as an organization continually finds ways to improve their EMS.

The entire process can take several months to several years depending on the size of the organization. If an organization is already ISO 9000-certified, the implementation of ISO 14001 does not take as long. When an organization is compliant, they can either register with a third-party

registrar or self-declare their compliance. The ISO 14001 standard is the only ISO 14000 standard that allows an organization to be registered or “certified.”

The Technical Committee (TC) behind ISO 14000 is TC 207.

ISO 9000

ISO 9000 is a series of standards, developed and published by the International Organization for Standardization (ISO), that define, establish, and maintain an effective quality system for manufacturing and service industries. The ISO 9000 standard is the most widely known and has perhaps had the most impact of the 13,000 standards published by the ISO. It serves many different industries and organizations as a guide to quality products, service, and management.

An organization can be ISO 9000-certified if it successfully follows the ISO 9000 standards for its industry. In order to be certified, the organization must submit to an examination by an outside assessor. The assessor interviews staff members to ensure that they understand their part in complying with the ISO 9000 standard, and the assessor examines the organization’s paperwork to ensure ISO 9000 compliance. The assessor then prepares a detailed report that describes the parts of the standard the organization missed. The organization then agrees to correct any problems within a specific time frame. When all problems are corrected, the organization can then be certified. Today, there are approximately 350,000 ISO 9000-certified organizations in over 150 countries.

The Technical Committee (TC) behind ISO 9000 is TC 176.

ISO 9660

An ISO 9660 file system is a standard **CD-ROM file system** that allows you to read the same CD-ROM whether you’re on a PC, Mac, or other major computer platform. The standard, issued in 1988, was written by an industry group named High Sierra. Almost all computers with CD-ROM drives can read files from an ISO 9660 file system.

There are several specification levels. In Level 1, file names must be in the 8.3 format (no more than eight characters in the name, no more than three characters in the suffix) and in capital letters. Directory names can be no longer than eight characters. There can be no more than eight nested directory levels. Level 2 and 3 specifications allow file names up to 32 characters long.

ISO date format

The **International Organization for Standardization (ISO)** date format is a standard way to express a numeric calendar date that eliminates ambiguity. For example, North Americans usually write the month before the date. Europeans write the date before the month as in “30.3.1998” for March 30, 1998. The separators used between numbers

also vary between countries. The question of how to express a date in numbers that precedes “1/1/1” also arises (how to express a date that is “B.C.”). ISO 8601 provides a standard cross-national approach that says:

- A general-to-specific approach, forming a date that is easier to process—thus, the year first, followed by month, then day
- With each separated by a hyphen (“-”)
- Numbers less than 10 preceded by a leading zero
- Years expressed as “0” prior to year 1 and as “-1” for the year prior to year 0 (and so forth). Thus, March 30, 1998 would be: 1998-03-30.

To express whether the date reflects the **Julian calendar** or the **Gregorian calendar**, the date can be followed with a “J” or a “G”.

isochronous

In information technology, isochronous (from the Greek “equal” and “time”; pronounced “eye-SAH-krun-us”) pertains to processes that require timing coordination to be successful, such as voice and digital video transmission. A sound or picture going from a peripheral computer device or across a network into a computer or television set needs to arrive at close to the same rate of data flow as the source. In feeding digital image data from a peripheral device (such as a video camera) to a display mechanism within a computer, isochronous data transfer ensures that data flows continuously and at a steady rate in close timing with the ability of the display mechanism to receive and display the image data. (**FireWire**, the IEEE 1394 High Performance Serial Bus, includes an isochronous interface.)

Isochronous can be distinguished from **asynchronous**, which pertains to processes that proceed independently of each other until a dependent process has to “interrupt” the other process, and **synchronous**, which pertains to processes in which one process has to wait on the completion of an event in another process before continuing.

isotropic radiator

An isotropic radiator is a **transducer** that produces useful **electromagnetic field** output in all directions with equal intensity, and at 100-percent efficiency, in three-dimensional space. If used for signal reception, the device is equally sensitive in all directions. In **wireless** communications and broadcasting, the isotropic radiator (also called an isotropic **antenna**) is a theoretical ideal. It is sometimes referred to as a *point source*.

In wireless applications, an isotropic radiator can be approximated by constructing a single-turn square loop with a circumference of $\frac{1}{2}$ **wavelength**, and then giving the loop a half-twist along an axis that lies in the plane of the loop.

The isotropic radiator is useful primarily as a standard laboratory reference source. The behavior and performance of more complex antennas is measured against it. A **dipole antenna**, for example, has signal output and sensitivity approximately 2.15 **decibels** greater, in its favored directions, than the output and sensitivity of an isotropic antenna.

ISP

An ISP (Internet service provider) is a company that provides individuals and other companies access to the Internet and other related services such as Web site building and **virtual hosting**. An ISP has the equipment and the telecommunication line access required to have a **point-of-presence** on the Internet for the geographic area served. The larger ISPs have their own high-speed leased lines so that they are less dependent on the telecommunication providers and can provide better service to their customers. Among the largest national and regional ISPs are AT&T WorldNet, IBM Global Network, MCI, Netcom, UUNet, and PSINet.

ISPs also include regional providers such as New England's NEARNet and the San Francisco Bay area BARNet. They also include thousands of local providers. In addition, Internet users can also get access through online service providers (**OSP**) such as America Online and Compuserve.

The larger ISPs interconnect with each other through **MAE** (ISP switching centers run by MCI WorldCom) or similar centers. The arrangements they make to exchange traffic are known as **peering** agreements. There are several very comprehensive lists of ISPs world-wide available on the Web.

An ISP is also sometimes referred to as an IAP (Internet access provider). ISP is sometimes used as an abbreviation for *independent service provider* to distinguish a service provider that is an independent, separate company from a telephone company.

ISPF

ISPF (Interactive System Productivity Facility) is the **user interface** and supporting programs that come with IBM's **OS/390** operating system and that allow a company to configure and manage its system, add new system or application programs and test them, and access system files (data sets). ISPF consists of the Dialog Manager (DM), the Program Development Facility (PDF), and the Software Configuration and Library Management (SCLM) facility.

IBM also offers an ISPF that will run on an **OS/2** system so that developers can work "offline" from the OS/390.

ISPs

See "ISP"

ISRC

See "International Standard Recording Code"

ISV

An ISV (independent software vendor) makes and sells software products that run on one or more computer hardware or **operating system platforms**. The companies that make the platforms like Microsoft, IBM, Hewlett-Packard, Apple, and others encourage and lend support to ISVs, often with special "business partner" programs. In general, the more applications that run on a platform, the more value it offers to customers. Of course, platform manufacturers such as Microsoft and IBM make applications, too, but don't have the resources and, in many cases, the special knowledge required, to make them all. Think of all the programs that run on your Windows 2000 or Mac platform and you'll realize how many ISVs there are. Some ISVs focus on a particular operating system like IBM's small business **AS/400** for which there are thousands of ISV applications. Other ISVs specialize in a particular application area, such as engineering, and develop software primarily for high-end **UNIX**-based workstation platforms.

ISVs make and sell software that is added to platforms. Original equipment manufacturers (**OEMs**) use hardware platform components to build larger products. Value-added resellers (**VARs**) incorporate platform software into their own software product packages.

IT

IT (information technology) is a term that encompasses all forms of technology used to create, store, exchange, and use **information** in its various forms (business data, voice conversations, still images, motion pictures, multimedia presentations, and other forms, including those not yet conceived). It's a convenient term for including both telephony and computer technology in the same word. It is the technology that is driving what has often been called "the information revolution."

IT Infrastructure Library

See "ITIL"

Itanium

Itanium is Intel's first **microprocessor** that is based on the **64-bit** architecture known as **IA-64**. Developed under the code name of **Merced**, Itanium and its underlying **architecture** are expected to provide a foundation for the next-generation of software for the **server** and high-end **workstation** markets.

Intel plans to follow Itanium with additional IA-64 microprocessors, which have the code names of McKinley, Madison, and Deerfield.

In addition to supporting a 64-bit processor **bus** and a set of 28 **registers**, the 64-bit design allows access to a very large **memory** (VLM). In addition, the architecture exploits features in Explicitly Parallel Instruction Computing (**EPIC**), a joint Intel and Hewlett-Packard development effort. These provide advances in the **parallel processing** handling of computer **instructions** known as **predication** and **speculation**.

An additional Itanium feature includes a Level 3 (L3) **cache memory**, to supplement the current **L1** and **L2** cache memories found in most of today's microcomputers.

Most applications in use today are based on a 32-bit microprocessor architecture, and are designed for up to 4 gigabytes of memory. However, with application access to ever-larger databases becoming more important, many of the leading software and hardware suppliers in the computer industry have already begun to develop systems and applications for the Itanium and its ability to handle 64-bit address space.

One feature of Itanium is its use of a "smart **compiler**" to optimize how instructions are sent to the processor. This approach allows Itanium and future IA-64 microprocessors to process more instructions per clock cycle (IPCs). (IPCs can be used along with clock speed in terms of megahertz (MHz) to indicate a microprocessor's overall performance.)

Itanium is viewed by Intel and industry observers as a new level of hardware platform for the UNIX and Windows server market and also for the high-end PC workstation market with its memory- and graphics-intensive scientific, technical, and high-end graphics applications. Observers say Itanium-based servers will be especially suited for today's large enterprise computing environments with data warehouses and a requirement for intensive processing for complex queries and transactions.

Virtually all of the major manufacturers and suppliers of today's applications, high-end systems, operating systems, and computer hardware have endorsed Itanium and the IA-64 line of processors. More than 30 Itanium-based systems are expected to come to the marketplace in 2001. Some reports indicate that Itanium's IA-64 architecture will own its market through 2003, at which point some competitive "next-generation" microprocessors may begin to be seen. This window of opportunity allows Intel to capitalize on the popularity of IA-64, and to develop profitable **original equipment manufacturer** arrangements with other vendors, suppliers, and manufacturers in the computer industry. Itanium and IA-64 also support 32-bit applications.

iterative

Iterative (pronounced IT-ter-a-teev) is an adjective that means repetitious.

1) In computer programming, iterative is used to describe a situation in which a sequence of instructions can be executed multiple times. One pass through the sequence is called an

iteration. If the sequence of instructions is executed repeatedly, it is called a **loop**, and we say that the computer iterates through the loop.

2) In software development, iterative is used to describe a **heuristic** planning and development process where an **application** is developed in small sections called iterations. Each iteration is reviewed and critiqued by the software team and potential end-users; insights gained from the critique of an iteration are used to determine the next step in development. Data models or sequence diagrams, which are often used to map out iterations, keep track of what has been tried, approved, or discarded, and eventually serve as a kind of blueprint for the final product.

The challenge in iterative development is to make sure all the iterations are compatible. As each new iteration is approved, developers may employ a technique known as backwards engineering, which is a systematic review and check procedure to make sure each new iteration is compatible with previous ones. The advantage of using iterative development is that the end-user is involved in the development process. Instead of waiting until the application is a final product, when it may not be possible to make changes easily, problems are identified and solved at each stage of development. Iterative development is sometimes called circular or evolutionary development.

ITIL

ITIL (Information Technology Infrastructure Library) is a set of **best practices** standards for information technology (**IT**) service management. The United Kingdom's Central Computer and Telecommunications Agency (CCTA) created the ITIL in response to the growing dependence on information technology to meet business needs and goals. The ITIL provides businesses with a customizable framework of best practices to achieve quality service and overcome difficulties associated with the growth of IT systems. Hewlett-Packard and Microsoft are two businesses that use ITIL as part of their own best practices frameworks.

The ITIL is organized into "sets" of texts which are defined by related functions: service support, service delivery, managerial, software support, computer operations, security management, and environmental. In addition to texts, which can be purchased online, ITIL services and products include training, qualifications, software tools, and user groups such as the IT Service Management Forum (itSMF).

While owned by the CCTA since the mid-1980s, the ITIL is currently maintained and developed by The National Exam Institute for Informatics (EXIN), a non-proprietary and non-profit organization based in the Netherlands.

IT-ISAC

IT-ISAC (Information Technology Information Sharing and Analysis Center) is a facility founded in January 2001 by nineteen prominent IT industry companies (including

Oracle, IBM, EDS, and Computer Sciences) to serve as a central repository for security-related information. The group's purpose is to share each organization's information about security attacks and vulnerabilities among all the members. Member companies are expected to report information concerning security problems that they have or solutions to such problems that they have found. IT-ISAC should increase security levels and decrease monetary losses for its membership, at a time when—according to FBI estimates—the average security attack can cost an organization \$400,000.

President Clinton, in May 1998, issued Presidential Decision Directive 63, appealing to U.S. industry leaders to form information sharing and analysis groups to protect the nation's critical infrastructures against attacks, and establishing that purpose as a national security policy. Because much of the nation's infrastructure is privately owned and operated, effective security measures depend upon collaboration between the public and private sectors. In response to the directive, the Financial Services industry formed FS-ISAC (Financial Services Information Sharing and Analysis Center) in 1999. The effectiveness of the new group was demonstrated in February 2000, when it saved its membership from falling victim to the widespread **denial of service attacks** that affected much of the industry.

IT-ISAC is modeled on the financial services group, which distributes much of its information anonymously. Anonymity helps members to be more comfortable sharing information in a traditionally competitive industry where the security of organization-critical information has been very closely guarded.

ITU-T

The ITU-T (for Telecommunication Standardization Sector of the International Telecommunications Union) is the primary international body for fostering cooperative standards for telecommunications equipment and systems. It was formerly known as the **CCITT**. It is located in Geneva, Switzerland.

IVR

See "Interactive Voice Response"

IXC

See "interexchange carrier"

J/Direct

J/Direct is an application programming interface (API) from Microsoft that allows applications written in the Java programming language to make programming requests for Windows **operating system** services. Introduced in June 1997, J/Direct allows Java applications to make calls on Windows dynamic link libraries (DLLs). The existing DLLs do not need to be changed manually, because J/Direct automatically converts many commonly-used data types, according to Microsoft. Unlike earlier Java-to-Windows tools, J/Direct eliminates the need for programmers to write **wrapper** code around existing Windows applications.

J/Direct supports Microsoft's Windows 32-bit APIs and has been included in the software developer's kit (SDK) for Internet Explorer.

J2EE

J2EE (Java 2 Platform, Enterprise Edition) is a Java **platform** designed for the **mainframe**-scale computing typical of large **enterprises**. Sun Microsystems (together with industry partners such as IBM) designed J2EE to simplify application development in a **thin client tiered** environment. J2EE simplifies application development and decreases the need for programming and programmer training by creating standardized, reusable modular components and by enabling the tier to handle many aspects of programming automatically.

J2EE includes many components of the Java 2 Platform, Standard Edition (J2SE):

- The Java Development Kit (JDK) is included as the core language package.
- *Write Once Run Anywhere* technology is included to ensure **portability**.
- Support is provided for Common Object Request Broker Architecture (CORBA), a predecessor of Enterprise JavaBeans (EJB), so that Java objects can communicate with CORBA objects both locally and over a network through its *interface broker*.
- Java Database Connectivity 2.0 (JDBC), the Java equivalent to Open Database Connectivity (ODBC), is included as the standard interface for Java databases.
- A security model is included to protect data both locally and in Web-based applications.

J2EE also includes a number of components added to the J2SE model, such as the following:

- Full support is included for Enterprise JavaBeans. EJB is a server-based technology for the delivery of program components in an enterprise environment. It supports the Extensible Markup Language (XML) and has enhanced deployment and security features.
- The Java **servlet API** (application programming interface) enhances consistency for developers without requiring a graphical user interface (GUI).
- Java Server Pages (JSP) is the Java equivalent to Microsoft's **Active Server Pages** (ASP) and is used for dynamic Web-enabled data access and manipulation.

The J2EE architecture consists of four major elements:

- The J2EE Application Programming Model is the standard programming model used to facilitate the development of multi-tier, thin client applications.
- The J2EE Platform includes necessary policies and APIs such as the Java servlets and Java Message Service (JMS).
- The J2EE Compatibility Test Suite ensures that J2EE products are compatible with the platform standards.
- The J2EE Reference Implementation explains J2EE capabilities and provides its operational definition.

J2ME

J2ME (Java 2 Platform, Micro Edition) is a technology that allows programmers to use the Java programming language and related tools to develop programs for mobile **wireless** information devices such as cellular phones and personal digital assistants (PDAs). J2ME consists of programming specifications and a special **virtual machine**, the K Virtual Machine, that allows a J2ME-encoded program to run in the mobile device.

There are two programming specifications: Connected, Limited Device Configuration (CLDC) and the Mobile Information Device Profile (MIDP). CLDC lays out the application program interface (API) and virtual machine features needed to support mobile devices. MIDP adds to the CLDC the user interface, networking, and **messaging** details needed to interface with mobile devices. MIDP includes the idea of a **midlet**, a small Java application similar to an **applet** but one that conforms with CLDC and MIDP and is intended for mobile devices.

Devices with systems that exploit J2ME are already available and are expected to become even more available in the next few years.

Jabber

Also see **jabber (in networks)**.

Jabber is an initiative to produce an **open source**, XML-based **instant messaging** platform. Similar to the **Linux** and **Apache** projects, Jabber developers volunteer their time to work with the code over the Internet. As a result of their efforts, anyone can download the Jabber client and server for free. Creator Jeremie Miller first started Jabber.org in 1998.

Jabber operates differently than other proprietary instant messaging systems and works in a fashion similar to e-mail, using a distributed architecture. It adds a suffix to each address after the "@" sign (for instance user@msn) just like an **e-mail** addressing system. This enables a Jabber server to read addresses from different messaging systems and know where they can be found.

Even though Jabber is offered for free, many businesses need a contact for packaged software, technical support, and other services. That's the niche that Jabber.com hopes to fill. The company calls its relationship to Jabber.org similar to the one **Red Hat** has with Linux. Jabber.com has already released an instant messaging server that it vows will be compatible with many existing platforms, including America Online's closely guarded ICQ and AOL Instant Messenger. Miller now works for Jabber.com.

In September 2000, Jabber.com signed a deal with an open-source application service provider (**ASP**) and a wireless application developer to make a version for mobile devices.

jabber (in networks)

Also see **Jabber**, an open source program for instant messaging.

In networks, a jabber is any device that is handling electrical signals improperly, usually affecting the rest of the network. In an **Ethernet** network, devices compete for use of the line, attempting to send a signal and then retrying in the event that someone else tried at the same time. A jabber can look like a device that is always sending, effectively bringing the network to a halt. A jabber is usually the result of a bad network interface card (**NIC**). Occasionally, it can be caused by outside electrical interference.

jam

In an Ethernet network, a jam is a signal from one device to all other devices that a **collision** has occurred (it was trying to send a frame while another device was also trying to put a frame on the line). The jam signal results in additional collisions in any other frames in process of being put on the line and warns non-transmitting devices to wait. Effectively, a jam provides a way to force all devices to restart any bids to get control of the line.

jam sync

In **audio** (sound) production, jam sync is a mode of device synchronization using **SMPTE** time code in which a slave device can furnish its own timing during the time that a master device is temporarily unstable. Jam sync is usually an optional mode that the user can select.

In a basic SMPTE synchronization scenario, time code is fed from one device (the master) to a second device (the slave). The slave device follows the time locations as transmitted by the master device. If the master device goes to one hour and thirteen minutes (expressed as 01:13:00:00; Hours:Minutes:Seconds:Frames), the slave device follows it there.

The problem arises when the master device's SMPTE time code has an error in it, caused by a small bad portion of tape, for example. In most situations, the slave device would not know what to do for a split second since it has missing instructions from its host. It would stutter or stop completely.

By using jam syncing, the slave device can be instructed to ignore small dropouts of time code from the master, thus ensuring smooth synchronization. To do this, it generates its own time code whenever the master's time code is missing.

Japanese emoticons

In Japan, users have worked out **emoticons** (or keyboard "smiley faces") adapted to their culture. According to *The New York Times* (August 12, 1996), the Japanese are using emoticons even more than Westerners. Because their PC keyboards handle the two-byte characters of Kanji, users can choose between single- and double-byte versions of certain characters such as underscore characters, allowing a further degree of expression.

Here are some examples of Japanese emoticons:

^_^	Smile
^o^;>	Excuse me
^^;	Cold sweat
^o^	Happy
^o^	Exciting
(^_^)/	Banzai smiley

JAR file

A JAR (Java ARchive) file is a file that contains the **class**, image, and sound files for a **Java applet** gathered into a single file and compressed for faster **downloading** to your Web browser. An applet that comes as part of a Web page that you may happen to request may include several files, each of which would have to be downloaded along with the Web page. By putting the applet components in a single file and compressing that file, download time is saved.

When a programmer gets a Java program development kit, a small program or utility called “jar” is included. The jar utility lets you create, list, and extract the individual files from a JAR file. Ordinarily, a browser user will not need to “open” or view a JAR file directly. It is opened when the Web page is received and the applet is in some manner initiated.

The JAR format is based on the popular **zip** file format.

Java

Java is a programming language expressly designed for use in the **distributed** environment of the Internet. It was designed to have the “look and feel” of the C++ language, but it is simpler to use than C++ and enforces an **object-oriented programming** model. Java can be used to create complete applications that may run on a single computer or be distributed among servers and clients in a network. It can also be used to build a small application module or **applet** for use as part of a Web page. Applets make it possible for a Web page user to interact with the page.

The major characteristics of Java are:

- The programs you create are portable in a network. (See **portability**.) Your source program is compiled into what Java calls **bytecode**, which can be run anywhere in a network on a **server** or **client** that has a **Java virtual machine**. The Java virtual machine interprets the bytecode into code that will run on the real computer hardware. This means that individual computer platform differences such as instruction lengths can be recognized and accommodated locally just as the program is being executed. Platform-specific versions of your program are no longer needed.
- The code is **robust**, here meaning that, unlike programs written in C++ and perhaps some other languages, the Java objects can contain no references to data external to themselves or other known objects. This ensures that an instruction can not contain the address of data storage in another application or in the operating system itself, either of which would cause the program and perhaps the operating system itself to terminate or “crash.” The Java virtual machine makes a number of checks on each object to ensure integrity.
- Java is object-oriented, which means that, among other characteristics, an **object** can take advantage of being part of a **class** of objects and inherit code that is common to the class. Objects are thought of as “nouns” that a user might relate to rather than the traditional procedural “verbs.” A **method** can be thought of as one of the object’s capabilities or behaviors.
- In addition to being executed at the client rather than the server, a Java applet has other characteristics designed to make it run fast.
- Relative to C++, Java is easier to learn. (However, it is not a language you’ll pick up in an evening!)

Java was introduced by Sun Microsystems in 1995 and instantly created a new sense of the interactive possibilities of the Web. Both of the major Web browsers include a Java virtual machine. Almost all major operating system developers (IBM, Microsoft, and others) have added Java compilers as part of their product offerings.

The Java virtual machine includes an optional **just-in-time compiler** that dynamically compiles bytecode into executable code as an alternative to interpreting one bytecode instruction at a time. In many cases, the dynamic JIT compilation is faster than the virtual machine interpretation.

JavaScript should not be confused with Java. JavaScript, which originated at Netscape, is interpreted at a higher level, is easier to learn than Java, but lacks some of the portability of Java and the speed of bytecode. Because Java applets will run on almost any operating system without requiring recompilation and because Java has no operating system-unique extensions or variations, Java is generally regarded as the most strategic language in which to develop applications for the Web. (However, JavaScript can be useful for very small applications that run on the Web client or server.)

Java 2 Platform, Enterprise Edition

See “J2EE”

Java 2 Platform, Micro Edition

See “J2ME”

Java chip

The Java chip is a **microchip** that, when included in or added to a computer, will accelerate the performance of **Java** programs (including the **applets** that are sometimes included with Web pages). The special chip can execute all or some of the instructions in the Java **bytecode** directly without requiring interpretation by a software **virtual machine**.

The Java chip may be particularly important as part of **embedded systems** in **handheld** devices such as **smart phones**.

Java Database Connectivity

JDBC (Java Database Connectivity) is an application program interface (**API**) specification for connecting programs written in **Java** to the data in popular **database**. The application program interface lets you encode access request statements in structured query language (**SQL**) that are then passed to the program that manages the database. It returns the results through a similar interface. JDBC is very similar to the SQL Access Group’s Open Database Connectivity (**ODBC**) and, with a small “bridge” program, you can use the JDBC interface to access databases through

the ODBC interface. For example, you could write a program designed to access many popular database products on a number of **operating system platforms**. When accessing a database on a PC running Microsoft's Windows 2000 and, for example, a Microsoft Access database, your program with JDBC statements would be able to access the Microsoft Access database.

JDBC actually has two levels of interface. In addition to the main interface, there is also an API from a JDBC "manager" that in turn communicates with individual database product "drivers," the JDBC-ODBC bridge if necessary, and a JDBC network driver when the Java program is running in a network environment (that is, accessing a remote database).

When accessing a remote database, JDBC takes advantage of the Internet's file addressing scheme and a file name looks much like a Web page address (or **Uniform Resource Locator**). For example, a Java SQL statement might identify the database as:

```
jdbc:odbc://www.somecompany.com:400/databasefile
```

JDBC specifies a set of **object-oriented classes** for the programmer to use in building SQL requests. An additional set of classes describes the JDBC driver API. The most common SQL **data types**, mapped to Java data types, are supported. The API provides for implementation-specific support for **Microsoft Transaction Server** requests and the ability to commit or roll back to the beginning of a transaction.

Java Foundation Classes

Using the **Java** programming language, Java Foundation Classes (JFC) are pre-written code in the form of **class** libraries (coded routines) that give the programmer a comprehensive set of graphical user interface (**GUI**) routines to use. The Java Foundation Classes are comparable to the Microsoft Foundation Class (**MFC**) library. JFC is an extension of the original Java Abstract Windowing Toolkit (**AWT**). Using JFC and **Swing**, an additional set of program components, a programmer can write programs that are independent of the **windowing system** within a particular **operating system**.

Java Message Service

Java Message Service (JMS) is an application program interface (**API**) from Sun Microsystems that supports the formal communication known as **messaging** between computers in a network. Sun's JMS provides a common interface to standard messaging protocols and also to special messaging services in support of **Java** programs. Sun advocates the use of the Java Message Service for anyone developing Java applications, which can be run from any major operating system platform.

The messages involved exchange crucial data between computers—rather than between users—and contain information such as event notification and service requests.

Messaging is often used to coordinate programs in dissimilar systems or written in different programming languages.

Using the JMS interface, a programmer can invoke the messaging services of IBM's **MQSeries**, Progress Software's SonicMQ, and other popular messaging product vendors. In addition, JMS supports messages that contain serialized Java **object** and messages that contain Extensible Markup Language (**XML**) pages.

Java Naming and Directory Interface

See "JNDI"

Java Server Page

Java Server Page (JSP) is a technology for controlling the content or appearance of Web pages through the use of **servlets**, small programs that are specified in the Web page and run on the Web server to modify the Web page before it is sent to the user who requested it. Sun Microsystems, the developer of **Java**, also refers to the JSP technology as the Servlet application program interface (**API**). JSP is comparable to Microsoft's Active Server Page (**ASP**) technology. Whereas a Java Server Page calls a Java program that is executed by the Web server, an Active Server Page contains a **script** that is **interpreted** by a script interpreter (such as **VBScript** or **JScript**) before the page is sent to the user.

An HTML page that contains a link to a Java servlet is sometimes given the file name suffix of .JSP.

JavaBeans

JavaBeans is an **object-oriented programming** interface from Sun Microsystems that lets you build re-useable applications or program building blocks called **components** that can be deployed in a network on any major operating system platform. Like **Java applet**, JavaBeans components (or "**Beans**") can be used to give World Wide Web pages (or other applications) interactive capabilities such as computing interest rates or varying page content based on user or **browser** characteristics.

From a user's point-of-view, a component can be a button that you interact with or a small calculating program that gets initiated when you press the button. From a developer's point-of-view, the button component and the calculator component are created separately and can then be used together or in different combinations with other components in different applications or situations.

When the components or Beans are in use, the properties of a Bean (for example, the background color of a window) are visible to other Beans and Beans that haven't "met" before can learn each other's properties dynamically and interact accordingly.

Beans are developed with a Beans Development Kit (BDK) from Sun and can be run on any major operating system platform (Windows, UNIX, Mac) inside a number of application environments (known as *containers*), including browsers, word processors, and other applications.

To build a component with JavaBeans, you write language statements using Sun's **Java** programming language and include JavaBeans statements that describe component *properties* such as user interface characteristics and *events* that trigger a bean to communicate with other beans in the same container or elsewhere in the network.

Beans also have *persistence*, which is a mechanism for storing the state of a component in a safe place. This would allow, for example, a component (bean) to "remember" data that a particular user had already entered in an earlier user session.

JavaBeans gives Java applications the *compound document* capability that the OpenDoc and **ActiveX** interfaces already provide.

JavaScript

JavaScript is an **interpreted** programming or **script** language from Netscape. It is somewhat similar in capability to Microsoft's **Visual Basic**, Sun's **Tcl**, the UNIX-derived **Perl**, and IBM's **REX**. In general, script languages are easier and faster to code in than the more structured and **compiled** languages such as **C** and **C++**. Script languages generally take longer to process than compiled languages, but are very useful for shorter programs.

JavaScript is used in Web site development to do such things as:

- Automatically change a formatted date on a Web page
- Cause a linked-to page to appear in a popup window
- Cause text or a graphic image to change during a **mouse rollover**

JavaScript uses some of the same ideas found in **Java**, the compiled **object-oriented programming** derived from **C++**. JavaScript code can be imbedded in **HTML** pages and interpreted by the Web browser (or client). JavaScript can also be run at the server as in Microsoft's **Active Server Pages** before the page is sent to the requestor. Both Microsoft and Netscape browsers support JavaScript, but sometimes in slightly different ways.

Jaz drive

A Jaz drive is a small, portable **hard disk drive** used primarily for backing up and archiving personal computer files. The Jaz drive is sold by Iomega Corporation, the same company that developed the **Zip drive**. Both the Jaz drive and the disks come in two sizes, 1 **GB** and 2 **GB**. The two sizes look similar, but a 2 **GB** disk is not compatible with a 1 **GB** Jaz drive. The 2 **GB** Jaz drive can use both disk sizes.

Internal and external Jaz drives are available. The Jaz drive uses the Small Computer System Interface (**SCSI**) and requires a SCSI controller.

A Jaz drive comes with software to back up the hard disk, to record and playback voice, music and video files, to temporarily use the Jaz drive on another computer, and to duplicate Jaz disks using one Jaz drive. Jaz drives are also used to exchange files with others, to store unusually large files, and to keep certain files separate from files on your hard disk. The Jaz drive is different from a Zip drive in that the computer recognizes it as another hard disk, which allows the user to install and use applications from the Jaz drive. The Jaz drive runs at speeds near or equal to traditional hard disks.

JBOD

JBOD (for "just a bunch of disks," or sometimes "just a bunch of drives") is a derogatory term—the official term is "spanning"—used to refer to a computer's hard disks that haven't been configured according to the **RAID** (for "redundant array of independent disks") system to increase fault tolerance and improve data access performance.

The RAID system stores the same data redundantly on multiple disks that nevertheless appear to the **operating system** as a single disk. Although JBOD also makes the disks appear to be a single one, it accomplishes that by combining the drives into one larger logical one. JBOD doesn't deliver any advantages over using separate disks independently and doesn't provide any of the fault tolerance or performance benefits of RAID.

JCL

JCL (job control language) is a language for describing **jobs** (units of work) to the **MVS**, **OS/390**, and **VSE operating systems**, which run on IBM's **S/390 large server (mainframe)** computers. These operating systems allocate their time and space resources among the total number of jobs that have been started in the computer. Jobs in turn break down into job steps. All the statements required to run a particular program constitute a job step. Jobs are *background* (sometimes called **batch**) units of work that run without requiring user interaction (for example, print jobs). In addition, the operating system manages interactive (*foreground*) user requests that initiate units of work. In general, foreground work is given priority over background work.

One IBM manual compares a set of JCL statements to a menu order in a restaurant. The whole order is comparable to the job. Back in the kitchen, the chefs divide the order up and work on individual dishes (job steps). As the job steps complete, the meal is served (but it has to be served in the order prescribed just as some job steps depend on other job steps being performed first).

JCL statements mainly specify the input *data sets* (files) that must be accessed, the output data set to be created or updated, what resources must be allocated for the job, and the programs that are to run, using these input and output data sets. A set of JCL statements for a job is itself stored as a data set and can be started interactively. MVS and OS/390 provide an interactive menu-like interface, ISPF, for initiating and managing jobs.

In MVS and OS/390, the part of the operating system that handles JCL is called the Job Entry Subsystem (JES). There are two versions, JES2 and a later version with additional capabilities, JES3.

JDBC

See "Java Database Connectivity"

JEDEC SDRAM

JEDEC (Joint Electron Device Engineering Council) SDRAM is an industry standard synchronous DRAM. It has a dual-bank architecture and several burst mode accesses that can be preset. JEDEC SDRAM chips operate at either 83 MHz or 100 MHz. JEDEC SDRAM is also known as PC66 SDRAM because it was originally rated for 66 MHz bus operation and to distinguish it from Intel's PC100 architecture.

jello

See "ice"

JES

See "Job Entry Subsystem"

JES2

See "Job Entry Subsystem"

JES3

See "Job Entry Subsystem"

JFC

See "Java Foundation Classes"

JHTML

JHTML (Java within Hypertext Markup Language) is a standard for including a **Java** program as part of a Web page (a page written using the Hypertext Markup Language, or **HTML**). A Web site developer can write a small program using the Java programming language and insert the program within a Web page. When a user requests the page, the Web site server, observing a request for a file with the .html suffix, passes the code to a special Java program designed to handle JHTML. This program, called the PageCompileServlet, calls the Java **compiler**, which quickly

compiles the code. (If the code has previously been compiled by an earlier page request, this step is unnecessary.) The code is then executed, typically modifying the contents of the Web page in some way before it is sent to the requestor.

JHTML is comparable to Microsoft's **Active Server Page** and to **PHP** in that all are approaches to modifying a Web page at the server before it is sent rather than at the **client** (the user's Web browser) with **JavaScript**. To access a **database** from the Web page, the Java code might use the Java Database Connectivity (**JDBC**) interface.

JHTML requires installing a Java compiler on the Web server. JHTML is part of JavaSoft's Java WebServer Application Program Interface.

Jigsaw

Jigsaw is a **Web server** from the World Wide Web Consortium (**W3C**) that is designed for the purpose of demonstrating new Web **protocols** and other features. Jigsaw is written in the **Java** programming language and made available as **open source software**. You can download it from the W3C site in either a **UNIX** or a **Windows 2000** version.

Although Jigsaw is intended to be a demonstration platform rather than a fully capable Web server, the W3C reports that it performs as well as the **CERN** server and provides much of the usual Web server support such as **proxy server** capability, **virtual hosting**, and support for **common gateway interface**. Jigsaw can also be used for delivering pages built or modified with **Personal Home Page** and JSP scripts.

Jikes

Jikes is an **open source Java compiler** from IBM that adheres strictly to the Java specification and promises an "extremely fast" compilation. Although Sun Microsystems, the inventor of Java, offers its own proprietary compiler, IBM's compiler uses the open source idea, meaning that anyone can acquire IBM's Jikes **source code** for free and redistribute it with modifications (if these adhere to the Java specifications). Jikes is included as part of several different variations of **Linux**, including the popular version from Red Hat.

IBM says that Jikes adheres to both the Java Language Specification and the Java Virtual Machine Specification, and does not support subsets, supersets, or other variations of the language. In addition to fast compilation, Jikes analyzes source code that is being compiled for dependencies on other source code files that may be needed. Jikes is available for most major **operating system** platforms. IBM points out that Jikes is not a Java development environment, but just a Java compiler.

Jini

Jini (pronounced DJEE-nee like the Arabic word for “magician”) is a new idea that Sun Microsystems calls “spontaneous networking.” Using the Jini architecture, users will be able to plug printers, storage devices, speakers, and any kind of device directly into a network and every other computer, device, and user on the network will know that the new device has been added and is available. Each pluggable device will define itself immediately to a network device registry. When someone wants to use or access the resource, their computer will be able to download the necessary programming from it to communicate with it. No longer will the special device support software known as a **device driver** need to be present in an **operating system**. The operating system will know about all accessible devices through the network registry.

Jini can be viewed as the next step after the **Java** programming language toward making a network look like one large computer. Jini promises to enable manufacturers to make devices that can attach to a network independently of an operating system like Windows 95. Equipped with its own small, special-purpose and possibly microchip-embedded operating system, a printer could be plugged into a network and immediately shared by users at a mix of computers: Windows, Macintosh, UNIX. Mobile devices could be transported and easily plugged into a network so that others could use the device.

How It Works

Jini consists of four program layers:

- Directory Service
- JavaSpace
- Remote Method Invocation (RMI)
- Boot, Join, and Discover Protocol

Any device with an operating system that supports a Java can be plugged into the network. (For many devices, the operating system can be much smaller than Windows 2000, for example, since it is serving only the functions that device requires.) When a device is plugged into the Jini network, it is immediately registered by the Directory Service layer as a member of the network. Its necessary program **objects** are placed in a JavaSpace layer so that other network members can discover and download them when that network member wants to use the device. The actual communication with objects in JavaSpace is done using the Remote Method Invocation (RMI) interface and layer. The layer supporting the boot, join, and discover protocols enables devices, users, and applications to announce and register themselves and to discover others.

JIT

See “just-in-time compiler”

jitter

Jitter is the deviation in or displacement of some aspect of the pulses in a high-frequency **digital signal**. As the name suggests, jitter can be thought of as shaky pulses. The deviation can be in terms of amplitude, phase timing, or the width of the signal pulse. Another definition is that it is “the period frequency displacement of the signal from its ideal location.” Among the causes of jitter are electromagnetic interference (**EMI**) and crosstalk with other signals. Jitter can cause a display **monitor** to flicker; affect the ability of the **processor** in a personal computer to perform as intended; introduce clicks or other undesired effects in **audio** signals, and loss of transmitted data between network devices. The amount of allowable jitter depends greatly on the application.

JMS

See “Java Message Service”

JNDI

JNDI (Java Naming and Directory Interface) enables **Java** platform-based applications to access multiple naming and directory services. Part of the Java Enterprise application programming interface (**API**) set, JNDI makes it possible for developers to create **portable** applications that are enabled for a number of different naming and directory services, including: **file systems**; **directory** services such as Lightweight Directory Access Protocol (**LDAP**), **Novell Directory Services**, and Network Information System (**NIS**); and distributed object systems such as the Common Object Request Broker Architecture (**CORBA**), Java Remote Method Invocation (**RMI**), and Enterprise JavaBeans (**EJB**).

As an illustration of what JNDI does, Todd Sundsted (in a JavaWorld article, *JNDI overview, Part 1: An introduction to naming services*) uses the analogy of a library’s file system. Sundsted says that JNDI organizes and locates components within a distributed computing environment similarly to the way that card catalogs (and increasingly computer applications) organize and represent the locations of books within a library. A distributed application needs a means of locating components in the same way that the library patron needs a means of locating the book: Just rummaging around inside a library—or an application—is not an efficient way to find a particular object. JNDI makes it possible for application components to find each other. Because different naming and directory service providers can be seamlessly connected through the API, Java applications using it can be easily integrated into various environments and coexist with **legacy applications**. The current version, JNDI 1.2, was specified with input from Netscape, Novell, Tarantella, Sun, and BEA. JNDI is considered an industry standard.

job

In certain computer operating systems, a job is the unit of work that a computer **operator** (or a program called a **job scheduler**) gives to the **operating system**. For example, a job could be the running of an **application program** such as a weekly payroll program. A job is usually said to be run in **batch** (rather than interactive) mode. The operator or job scheduler gives the operating system a “batch” of jobs to do (payroll, cost analysis, employee file updating, and so forth) and these are performed in the **background** when time-sensitive interactive work is not being done. In IBM mainframe operating systems (**MVS**, **OS/390**, and successors) a job is described with job control language (**JCL**). Jobs are broken down into **job steps**. An example of a job step might be to make sure that a particular data set or database needed in the job is made accessible.

Typically, the development programmer who writes a program that is intended to be run as a batch job also writes the JCL that describes for the operating system how to run the job (for example, what data sets or databases it uses). The use of a job scheduler usually provides greater flexibility and the ability to monitor and report batch job operations.

A similar term is **task**, a concept usually applied to interactive work. A **multitasking** operating system serving one or more interactive users can at the same time perform batch jobs in the background.

job control language

See “JCL”

Job Entry Subsystem

Job Entry Subsystem (JES) is a subsystem of the **OS/390** and **MVS mainframe** operating systems that manages *jobs* (units of work) that the system does. Each job is described to the operating system by system administrators or other users in job control language (**JCL**). The operating system then sends the job to the JES program. The JES program receives the job, performs the job based on priority, and then purges the job from the system.

There are two versions, JES2 and JES3. JES3 allows central control of the processing of jobs using a common work queue. Both OS/390 and MVS provide an interactive menu for initiating and managing jobs.

job scheduler

A job scheduler is a program that enables an enterprise to schedule and, in some cases, monitor computer “batch” jobs (units of work, such as the running of a payroll program). A job scheduler can initiate and manage jobs automatically by processing prepared **job control language** statements or through equivalent interaction with a human operator.

Today’s job schedulers typically provide a graphical user interface and a single point of control for all the work in a **distributed** network of computers.

Some features that may be found in a job scheduler include:

- Continuously automatic monitoring of jobs and completion notification
- Event-driven job scheduling
- Performance monitoring
- Report scheduling

job step

In certain computer operating systems, a job step is part of a **job**, a unit of work that a computer **operator** (or a program called a **job scheduler**) gives to the **operating system**. For example, a job could be the running of an **application program** such as a weekly payroll program. A job is usually said to be run in **batch** (rather than interactive) mode. The operator or job scheduler gives the operating system a “batch” of jobs to do (payroll, cost analysis, employee file updating, and so forth) and these are performed in the **background** when time-sensitive interactive work is not being done. In IBM mainframe operating systems (**MVS**, **OS/390**, and successors) a job is described with job control language (**JCL**). Jobs are broken down into **job steps**. An example of a job step might be to make sure that a particular data set or database needed in the job is made accessible.

John von Neumann

John von Neumann was the scientist who conceived a fundamental idea that serves all modern computers—that a computer’s **program** and the **data** that it processes do not have to be fed into the computer while it is working, but can be kept in the computer’s **memory**—a notion generally referred to as *the stored-program computer*. In his short life, von Neumann became one of the most acclaimed and lauded scientists of the 20th century. He left an indelible mark on the fields of mathematics, quantum theory, game theory, nuclear physics, and computer science. Born in Budapest, von Neumann was a child prodigy who went on to study chemistry in Berlin and Zurich, where he earned a Diploma in Chemical Engineering in 1926. His doctorate in mathematics (on set theory) from the University of Budapest followed in the same year. After lecturing at Berlin and Hamburg, von Neumann emigrated to the U.S. in 1930 where he worked at Princeton and was one of the founding members of the Institute for Advanced Studies.

At Princeton, von Neumann lectured in the nascent field of **quantum theory** and through his work on rings of operators (later renamed Neumann algebras) he helped develop the mathematical foundations of that theory which were unveiled in the paper “*Mathematische Grundlagen der*

Quantenmechanik” (1932). His seminal publication on game theory, *“Theory of Games and Economic Behaviour”* was published in 1934 with co-author Oskar Morgenstern.

Spurred by an interest in hydrodynamics and the difficulty of solving the non-linear partial differential equations involved, von Neumann turned to the emerging field of computing. His first introduction to computers was Howard Aiken’s Harvard Mark I. As a consultant to Eckert and Mauchly on the ENIAC, he devised a concept for computer architecture that remains with us to this day. Known subsequently as the “von Neumann architecture,” the stored-program computer (where both the instructions and the data they operate upon reside together in memory) with its central controller, I/O, and memory was outlined in a “Draft Report” and paved the way for the modern era of computing. von Neumann was a pioneer in the field of cellular automata (an n-dimensional array of cells where the contents of a cell depend of the contents of neighboring cells) and also popularized the **binary digit** as the unit of computer memory.

von Neumann was constantly busy with both his extensive consulting career and his varied research interests. Among his employers was the U.S. military, for whom he worked on the development of the hydrogen bomb. He received the Enrico Fermi award in 1956, the latest in a long line of honors (including 7 honorary doctorates and 2 Presidential Awards). John von Neumann died on February 8, 1957 in Washington D.C.

Joint Photographic Experts Group

See “JPEG”

Jolt

Jolt, an American soft drink that contains the equivalent of two cups of coffee, has a following with programmers, college students, Internet surfers, and anyone else who needs to keep awake in the late night or early morning hours. One of our contributors describes it as “the fuel on which the Internet is run.” A typical can or bottle of Jolt contains about twice the amount of caffeine as Pepsi Cola or Coca Cola.

Yahoo lists a number of Web sites created by Jolt devotees.

joule

The joule (pronounced DJOOL) is the standard unit of **energy** in electronics and general scientific applications. One joule is defined as the amount of energy exerted when a force of one **newton** is applied over a displacement of one meter. One joule is the equivalent of one watt of **power** radiated or dissipated for one second.

In some applications, the British thermal unit (**Btu**) is used to express energy. One Btu is equivalent to approximately 1055 joules.

journaling file system

A journaling file system is a fault-resilient **file system** in which data integrity is ensured because updates to directories and bitmaps are constantly written to a serial log on disk before the original disk log is updated. In the event of a system failure, a full journaling filesystem ensures that the data on the disk has been restored to its pre-crash configuration. It also recovers unsaved data and stores it in the location where it would have gone if the computer had not crashed, making it an important feature for mission-critical applications.

Not all operating systems provide the same journaling technology. Windows NT offers a less robust version of the full system. If your Windows NT system crashes, you may not lose the entire disk volume, but you will likely lose all the data that hadn’t yet been written to the disk prior to the crash. By the same token, the default Linux system, ext2fs, does not journal at all. That means, a system crash—although infrequent in a Linux environment—can corrupt an entire disk volume.

However, XFS, a journaling file system from Silicon Graphics, became a part of the open-source community in 1999 and, therefore, has had important implications for Linux developers, who previously lacked such insurance features. Capable of recovering from most unexpected interruptions in less than a second, XFS epitomizes the high-performance journaling filesystem of the future.

The earliest journaling file systems, created in the mid-1980s, included Veritas, Tolerant, and IBM’s JFS. With increasing demands being placed on file systems to support terabytes of data, thousands upon thousands of files per directory and 64-bit capability, it is expected that interest will continue to grow in high-performance journaling file systems like XFS.

JPEG

A JPEG (pronounced JAY-peg) is a graphic image file created by choosing from a range of **compression** qualities (actually, from one of a suite of compression **algorithms**). When you create a JPEG or convert an image from another format to a JPEG, you are asked to specify the quality of image you want. Since the highest quality results in the largest file, you can make a trade-off between image quality and file size. Formally, the JPEG file format is **ISO** standard 10918. The JPEG scheme includes 29 distinct coding processes although a JPEG implementor may not use them all. JPEG is an acronym for Joint Photographic Experts Group, the committee that established the baseline algorithms.

Together with the Graphic Interchange Format (**GIF**) and Portable Network Graphics (**PNG**) file formats, the JPEG is one of the image file formats supported on the World Wide Web, usually with the file suffix of “.jpg”. You can create a **progressive JPEG** that is similar to an **interlaced GIF**.

JScript

JScript is a **script** language from Microsoft that is expressly designed for use within Web pages. It adheres to the **ECMAScript** standard and is basically Microsoft's equivalent to Netscape's earlier and more widely used **JavaScript**.

JSP

See "Java Server Page"

Julian calendar

The Julian calendar was the 365-day calendar that Julius Caesar made official in 46 B.C. It replaced a calendar based on lunar cycles. The Julian calendar provided for a leap year with an extra day every four years. Thus, the Julian calendar included an average of 365.25 days each year. By 1582 A.D., however, the Julian calendar had become out of step with the seasonal cycle by 10 days. The adjustment, ordered by Pope Gregory XIII in October, 1582, subtracted ten days from the calendar. The new **Gregorian calendar** removes a leap year every one hundred years except for years divisible by four hundred.

The Julian calendar has no relation to the **Julian date** format sometimes used in computing.

Julian date

1) Not to be confused with the **Julian calendar**, a Julian date or day number is the number of elapsed days since the beginning of a cycle of 7,980 years invented by Joseph Scaliger in 1583. The purpose of the system is to make it easy to compute an integer (whole number) difference between one calendar date and another calendar date. The 7,980 year cycle was derived by combining several traditional time cycles (solar, lunar, and a particular Roman tax cycle) for which 7,980 was a common multiple. The starting point for the first Julian cycle began on January 1, 4713 B.C. (**Gregorian calendar**—expressed in the ISO date format as "-4713-01-01 G") and will end on January 22, 3268 (3268-01-22 G). The following day will begin the first day of the second Julian date period (or 7,980 year cycle).

A Julian date or day number for a certain time of day on January 9, 2001, looked like this:

2451919.3423000001348555

meaning 2,451,919 elapsed days since the beginning of the Julian cycle. The ".3423000001348555" represented the time of day ("15:12:54 EST").

It is not certain whether the Julian date or day number system was named after Joseph Scaliger's father, Julius Caesar Scaliger, or after the Julian calendar. Julian day numbers are widely used in astronomy.

2) Commonly in computer programming, Julian date has been corrupted to mean the number of elapsed days since the beginning of a particular year. For example, in this usage, the Julian date for the calendar date of 1998-02-28 would be day 59.

jumbogram

Using the Internet Protocol version 6 (**IPv6**), a jumbogram is a transmission **packet** that contains a **payload** larger than 65,535 eight-bit bytes (also known as **octets**).

jump page

1) In Web site design, jump page is a term that is sometimes used to describe a Web site page that provides a "jumping off" point for users who need to locate information on the Web quickly and efficiently. Thus, a **portal** site or the **home page** for a site that specializes in gathering resources for a specific area of interest might be referred to as jump pages. **whatis.com** and other **TechTarget.com** sites can be considered jump pages for IT-specific information on the Web.

2) In Web site maintenance, a jump page can be a page that is posted temporarily to redirect the user when the page's address (its **URL**) has been changed.

3) In Internet advertising and marketing, a jump page (also called a landing page) is a Web page that is posted temporarily to capture the user's attention as a promotion or lead-in to a Web site. A jump page may be a **splash page** that contains a **Flash** animation. According to industry expert Robbin Zeff, a jump page on the Web is temporary, it is directly related to products or services that are currently being promoted, and it is designed to reinforce other ad promotions the user may have been exposed to.

jumper setting

1) In a computer, a jumper is a pair of prongs that are electrical contact points set into the computer **motherboard** or an **adapter card**. When you set a jumper, you place a plug on the prongs that completes a contact. Jumper settings tell the computer how it is configured and what operations can be performed. Computers come with jumpers preset. Instructions are sometimes provided so that the owner can reset the jumpers when new equipment is added. The latest trend, however, is **plug and play** equipment that does not require manual setting of jumpers. A group of jumpers is sometimes called a *jumper block*.

Finding the right jumper settings for a particular computer configuration usually requires having some technical information that comes with each product for which a

jumper setting has to be set or changed. Where this information isn't available, you may be able to find information at the Web site of the manufacturer.

2) In electronic test equipment, a jumper cable is used to make a temporary contact between two points for the purpose of testing a circuit.

just-in-time compiler

In the **Java** programming language and environment, a just-in-time (JIT) compiler is a program that turns Java **bytecode** (a program that contains instructions that must be interpreted) into instructions that can be sent directly to the **processor**. After you've written a Java program, the source language statements are compiled by the Java **compiler** into *bytecode* rather than into code that contains instructions that match a particular hardware platform's processor (for example, an Intel **Pentium** microprocessor or an IBM System/390 processor). The bytecode is platform-independent code that can be sent to any platform and run on that platform.

In the past, most programs written in any language have had to be recompiled, and sometimes, rewritten for each computer platform. One of the biggest advantages of Java is that you only have to write and compile a program once. The Java on any platform will interpret the compiled bytecode into instructions understandable by the particular processor. However, the virtual machine handles one bytecode instruction at a time. Using the Java just-in-time compiler (really a second compiler) at the particular system platform compiles the bytecode into the particular system code (as though the program had been compiled initially on that platform). Once the code has been (re-)compiled by the JIT compiler, it will usually run more quickly in the computer.

The just-in-time compiler comes with the virtual machine and is used optionally. It compiles the bytecode into platform-specific executable code that is immediately executed. Sun Microsystems suggests that it's usually faster to select the JIT compiler option, especially if the method executable is repeatedly reused.

K Desktop Environment

K Desktop Environment (KDE) is an **Open Source** graphical **desktop** environment for **UNIX workstations**. Initially called the Kool Desktop Environment, KDE is an ongoing project with development taking place on the Internet and discussions held through the official KDE mailing list, numerous newsgroups, and Internet Relay Chat (**IRC**) channels. KDE has a complete graphical user interface (**GUI**) and includes a file manager, a window manager, a help system, a configuration system, tools and utilities, and several **applications**. The most popular suite of KDE applications is KOffice, which includes a word processor, a spreadsheet application, a presentation application, a **vector** drawing application, and image editing tools. KOffice was released with KDE version 2.0 in October 2000. On December 5, 2000, KDE 2.0.1 was released.

Matthias Ettrich launched the KDE project in October 1996 with the goal of making the UNIX **platform** more attractive and easy to use for computer users who are familiar with a graphical interface instead of typed commands. Today, KDE is used with **Linux**, **Solaris**, FreeBSD, OpenBSD, and LinuxPPC. Several hundred software programmers from all over the world contribute to the development of KDE.

K-12

K-12, a term used in education and educational technology in the United States, Canada, and possibly other countries, is a short form for the publicly-supported school grades prior to college. These grades are kindergarten (K) and the 1st through the 12th grade (1-12). (If the term were used, "13th grade" would be the first year of college.)

Most communities in the United States and Canada (and wherever else the term is used) are just beginning to provide modern information technology at the K-12 levels.

K6

K6 (referred to by its manufacturer as AMD-K6) is a line of **microprocessors** from **AMD** that compete with Intel's **Pentium** series of microprocessors. The successor to the K6 is the **Athlon**.

K7

K7 was the development name for the **Athlon** personal computer **microprocessor** from **AMD**, the microprocessor and **flash memory** maker. The Athlon became the first microprocessor for mainstream PCs to support a 200 **MHz** system **bus** and to achieve a 1 **gigahertz clock speed**. As Athlon, different versions of the K7 are built with either the

0.25 **micron** infrastructure that is used in the popular **K6** microprocessor or, as for the 1 GHz model, with a 0.18 micron infrastructure.

Katmai

See "Pentium 3"

Kbps

***Note:** In international English outside the U.S., the equivalent usage is "kpbs" or "kbits s⁻¹."

In the U.S., Kbps stands for **kilobits** per second (thousands of bits per second) and is a measure of **bandwidth** (the amount of data that can flow in a given time) on a data transmission medium. Higher bandwidths are more conveniently expressed in **megabits** per second (**Mbps**, or millions of bits per second) and in **gigabits** per second (**Gbps**, or billions of bits per second).

See "KISS Principle"

keiretsu

In corporate culture, keiretsu refers to a uniquely Japanese form of corporate organization. A keiretsu is a grouping or family of affiliated companies that form a tight-knit alliance to work toward each other's mutual success. The keiretsu system is also based on an intimate partnership between government and businesses. It can best be understood as the intricate web of relationships that links banks, manufacturers, suppliers, and distributors with the Japanese government.

These ironclad corporate alliances have caused much debate and have been called "government-sponsored cartels." While some think keiretsu are a menace to trade, others see them as a model for change. Features common to most keiretsu include "main bank," stable shareholding, and seconded directors. Some keiretsu concepts have no

American parallel such as “general trading company.” The keiretsu system is one of the profound differences between Japanese and U.S. business structures.

Keiretsu operate globally and are integrated both vertically and horizontally. They are organized around their own trading companies and banks. Each major keiretsu is capable of controlling nearly every step of the economic chain in a variety of industrial, resource and service sectors.

There are horizontal and vertical keiretsu. Horizontal keiretsu are headed by major Japanese banks and include the “Big Six”—Mitsui, Mitsubishi, Sumitomo, Fuyo, Sanwa, and Dai-Ichi Kangyo Bank Groups. Vertical keiretsu are industrial groups connecting manufacturers and part suppliers or manufacturers, wholesalers and retailers. These verticle keiretsu include car and electronics producers (Toyota, Nissan, Honda–Matsushita, Hitachi, Toshiba, Sony) and their “captive” subcontractors. Distribution keiretsu, a subgroup of vertical keiretsu, control much of Japanese retailing, determining what products will appear in stores and showrooms—and at what price.

kelvin

The kelvin (abbreviation K), less commonly called the degree Kelvin (symbol, °K), is the International System (SI) unit of thermodynamic temperature. One kelvin is formally defined as $1/273.16$ (3.6609×10^{-3}) of the thermodynamic temperature of the triple point of pure water (H₂O).

The kelvin scale differs from the more familiar Celsius or centigrade (°C) temperature scale; there is no such thing as a below-zero Kelvin figure. A temperature of 0 K represents absolute zero, the absence of all heat. However, the size of the kelvin “degree” is the same as the size of the Celsius “degree.” A change of plus-or-minus 1 °C is the same as a change of plus-or-minus 1 K.

At standard Earth-atmospheric sea-level pressure, water freezes at 0 °C or +273.15 K, and boils at +100 °C or +373.15 K. A temperature of 0 K thus corresponds to –273.15 °C. To convert a kelvin temperature figure to Celsius, subtract 273.15. To convert a Celsius temperature figure to kelvin, add 273.15.

Kerberos

Kerberos is a secure method for authenticating a request for a service in a computer network. Kerberos was developed in the Athena Project at the Massachusetts Institute of Technology (MIT). The name is taken from Greek mythology; Kerberos was a three-headed dog who guarded the gates of Hades. Kerberos lets a user request an encrypted “ticket” from an **authentication** process that can then be used to request a particular service from a server. The user’s **password** does not have to pass through the network. A version of Kerberos (client and server) can be downloaded from MIT or you can buy a commercial version.

Briefly and approximately, here’s how Kerberos works:

1. Suppose you want to access a server on another computer (which you may get to by sending a **Telnet** or similar login request). You know that this server requires a Kerberos “ticket” before it will honor your request.
2. To get your ticket, you first request authentication from the Authentication Server (AS). The Authentication Server creates a “session key” (which is also an encryption key) basing it on your password (which it can get from your user name) and a random value that represents the requested service. The session key is effectively a “ticket-granting ticket.”
3. You next send your ticket-granting ticket to a ticket-granting server (TGS). The TGS may be physically the same server as the Authentication Server, but it’s now performing a different service. The TGS returns the ticket that can be sent to the server for the requested service.
4. The service either rejects the ticket or accepts it and performs the service.
5. Because the ticket you received from the TGS is time-stamped, it allows you to make additional requests using the same ticket within a certain time period (typically, eight hours) without having to be reauthenticated. Making the ticket valid for a limited time period make it less likely that someone else will be able to use it later.

The actual process is much more complicated than just described. The user procedure may vary somewhat according to implementation.

Kermit

Kermit is a popular file transfer and management **protocol** and suite of communications software programs with advantages over existing Internet protocols such as **File Transfer Protocol** and **Telnet**. It is **freeware**, developed and maintained by members of the Kermit Project at Columbia University. (However, you’re invited to purchase shrink-wrapped versions and/or the manuals to help support the project.) The Kermit protocol is described as “fast, robust, extensible, tunable, and medium-independent.” In addition to the protocol support, the Kermit suite includes **terminal emulation**, character-set translation, and scripting. The suite can be installed on almost any **operating system**, including Windows, UNIX, DOS, VMS, OS/2, and a number of mainframe operating systems. Most versions support both direct or dialed serial connections (with a modem) and network connections (**Telnet** and often others such as Rlogin, LAT, or X.25).

Some advantages of Kermit are:

- You can write a script that will allow a sequence of file transfers to happen with a single command
- You can transfer an entire file directory and its subdirectories with a single command
- Text and binary files can be sent in the same file transfer

kernel

The kernel is the essential center of a computer **operating system**, the core that provides basic services for all other parts of the operating system. A synonym is *nucleus*. A kernel can be contrasted with a **shell**, the outermost part of an operating system that interacts with user commands. *Kernel* and *shell* are terms used more frequently in **UNIX** and some other operating systems than in IBM mainframe systems.

Typically, a kernel (or any comparable center of an operating system) includes an interrupt handler that handles all requests or completed I/O operations that compete for the kernel's services, a scheduler that determines which programs share the kernel's processing time in what order, and a supervisor that actually gives use of the computer to each process when it is scheduled. A kernel may also include a manager of the operating system's address spaces in memory or storage, sharing these among all components and other users of the kernel's services. A kernel's services are requested by other parts of the operating system or by **applications** through a specified set of program interfaces sometimes known as *system calls*.

Because the code that makes up the kernel is needed continuously, it is usually loaded into computer storage in an area that is protected so that it will not be overlaid with other less frequently used parts of the operating system.

The kernel is not to be confused with the basic input/output system (**BIOS**).

Some kernels have been developed independently for use in any operating system that wants to use it. A well-known example is the *Mach kernel*, developed at Carnegie-Mellon University, and currently used in a version of the **Linux** operating system for Apple's PowerMac computers.

key

In cryptography, a key is a variable value that is applied using an **algorithm** to a string or **block** of unencrypted text to produce **encrypted** text, or to decrypt encrypted text. The length of the key is a factor in considering how difficult it will be to decrypt the text in a given message.

keyboard

On most computers, a keyboard is the primary **text** input device. (The **mouse** is also a primary input device but lacks the ability to easily transmit textual information.) The keyboard also contains certain standard function keys, such

as the Escape key, tab and cursor movement keys, shift and control keys, and sometimes other manufacturer-customized keys.

The computer keyboard uses the same key arrangement as the mechanical and electronic typewriter keyboards that preceded the computer. The standard arrangement of alphabetic keys is known as the Qwerty (pronounced KWEHR-tee) keyboard, its name deriving from the arrangement of the five keys at the upper left of the three rows of alphabetic keys. This arrangement, invented for one of the earliest mechanical typewriters, dates back to the 1870s. Another well-known key arrangement is the Dvorak (pronounced duh-VOR-ak, not like the Czech composer) system, which was designed to be easier to learn and use. The Dvorak keyboard was designed with the most common consonants on one side of the middle or home row and the vowels on the other side so that typing tends to alternate key strokes back and forth between hands. Although the Dvorak keyboard has never been widely used, it has adherents.

Because many keyboard users develop a **cumulative trauma disorder**, such as *carpal tunnel syndrome*, a number of **ergonomic** keyboards have been developed. Approaches include keyboards contoured to alleviate stress and foot-driven pedals for certain keys or keyboard functions.

kHz

The kilohertz, abbreviated kHz or KHz*, is a unit of alternating current (**AC**) or electromagnetic (EM) wave frequency equal to one thousand **hertz** (1,000 Hz). The unit is also used in measurements or statements of signal **bandwidth**.

An AC signal having a frequency of 1 kHz is within the range of human hearing. If a signal at this frequency is input to a headset or loudspeaker, the resulting tone has a pitch that falls into the so-called "audio midrange." An EM signal at a frequency of 1 kHz has a **wavelength** of 300 kilometers, or about 190 miles. The standard amplitude-modulation (**AM**) broadcast band extends from 535 kHz to 1,605 kHz. Some EM transmissions are made at millions of kHz.

The kilohertz is a relatively small unit of frequency; more common units are the **MHz**, equal to 1,000,000 Hz or 1,000 kHz, and the **GHz**, equal to 1,000,000,000 Hz or 1,000,000 kHz.

The kilohertz is often used to specify bandwidth for **digital** as well as **analog** signals. The bandwidth of a digital signal, in kilohertz, is related to the data speed in **bits per second**. In general, the greater the data speed, the larger the bandwidth. Data speed is not, however, the same thing as bandwidth. A modem operating at a speed of 28,800 bps has, in a certain sense, a nominal frequency of 28.8 kHz. But the bandwidth is generally much smaller, because it depends on variations in the individual data characters, not on the number of data bits per unit time.

*The engineer's society, **IEEE**, and most other sources prefer "kHz" to "KHz." This apparently makes it less likely that users will confuse "kilo" (decimal 1,000) with the computer "K" (1,024).

killer app

A "killer app" is jargon in the computer industry for an **application program** that intentionally or unintentionally gets you to make the decision to buy the system the application runs on. A classic example of a killer app was the **spreadsheet** program, the first of which was called VisiCalc, followed later by Lotus 1-2-3. The spreadsheet application helped introduce the personal computer into the department level of large and small businesses. A killer app can refer to a generic type of application that hasn't existed before, to a particular product that first introduces a new application type, or to any application with wide appeal.

When a new kind of computer hardware product comes out, such as a hand-held computer, manufacturers offer or hope to entice others to develop what they believe will be the killer app that will motivate potential customers to buy the new computer. In recent ads, IBM says that the killer app for **e-business** (which is both a concept and an array of Internet products and services that IBM sells) is "an application deployed over the Web that makes it easier to do the things you already do." Clearly, the Web **browser** and the Internet servers it communicates with became the killer app of the 1990s.

kilobit

In data communications, a kilobit is a thousand (10^3) **bits**. It's commonly used for measuring the amount of data that is transferred in a second between two telecommunication points. Kilobits per second is usually shortened to **Kbps**.*

Some sources define a kilobit to mean 1,024 (that is, 2^{10}) bits. Although the bit is a unit of the binary number system, bits in data communications are discrete signal pulses and have historically been counted using the decimal number system. For example, 28.8 kilobits per second (**Kbps**) is 28,800 bits per second. Because of computer architecture and memory address boundaries, bytes are always some multiple or exponent of two. See **kilobyte**, etc.

***Note:** In international English outside the U.S., the equivalent usage is "kbps" or "kbits s⁻¹."

kilobits per second

See "Kbps"

kilobyte

As a measure of computer **memory** or storage, a kilobyte (KB or Kbyte*) is approximately a thousand **bytes** (actually, 2 to the 10th power, or decimal 1,024 bytes).

***Note:** In international English outside the U.S., the equivalent usage is sometimes "kbyte."

kilogram per meter cubed

The kilogram per meter cubed (symbolized kg/m³) is the standard unit of material density in the International System of Units (SI). Material density is expressed directly in base SI units, and cannot be further reduced.

A substance with a density of 1 kg/m³ is extremely light for its size. Even styrofoam or bubble-wrap has a density greater than this. A cubic meter of water has a mass of about 1000 kg, more than a conventional English ton in the gravitational field of the earth.

Alternative units are often used to express density. The most common of these is the gram per centimeter cubed (g/cm³). A substance with a density of 1 g/cm³ has a density of 1000 kg/m³. Conversely, a substance with a density of 1 kg/m³ has a density of 0.001 g/cm³.

Also see **kilogram**, **meter**, **specific gravity**, and **SI** (International System of Units).

kilogram

The kilogram (abbreviation, kg) is the International System of Units (**SI**) unit of mass. It is defined as the mass of a particular international prototype made of platinum-iridium and kept at the International Bureau of Weights and Measures. It was originally defined as the mass of one liter (10^{-3} cubic meter) of pure water.

At the Earth's surface, a mass of 1 kg weighs approximately 2.20 pounds (lb). Conversely, an object that weighs 1 lb at the Earth's surface has a mass of approximately 0.454 kg. There is a qualitative as well as a quantitative difference between kilograms and pounds. Kilograms denote mass, but pounds denote weight, the force a mass exerts against a barrier in the presence of an acceleration field acting perpendicular to the barrier. On the surface of Mars, where the gravitational acceleration is 37 percent of that on the surface of the Earth, a mass of 1 kg weighs 0.814 lb. In orbit, or in a vehicle coasting through space, the net acceleration is zero and a mass of 1 kg has no weight. In other words, it is weightless.

Mass is often specified in smaller units than the kilogram, by changing the power-of-10 **prefix multiplier**. A mass of one gram (1 g) is 10^{-3} kg. A mass of one milligram (1 mg) is 10^{-6} kg, or 10^{-3} g. A mass of one microgram (1 μ g) is 10^{-9} kg, or 10^{-6} g. A mass of one nanogram (1 ng) is 10^{-12} kg, or 10^{-9} g.

kiosk

In information technology, a kiosk (pronounced KEE-ahsk) is a small physical structure (often including a computer and a display screen) that displays information for people walking by. Kiosks are common near the entrances of shopping malls in North America where they provide shoppers with directions. Kiosks are also used at trade shows and professional conferences. The word is of Turkish and earlier Persian origin, where it meant an outdoor pavilion or a portico. The kiosks best known to travellers are those that display show and movie posters on the streets of Paris.

More sophisticated kiosks let users interact and include touch screens, sound, and motion video. A number of companies specialize in creating **multimedia** kiosks. A simple kiosk can be created using **HTML** pages and graphics, setting the typesize large enough to attract people from a short distance, and removing the Web browser's tool bar so that the display screen is effectively in "kiosk mode." The presentation can be designed to simply loop through a series of pages or to allow user interaction and exploration. Having a separate printed sign that invites people to your home-made kiosk may help.

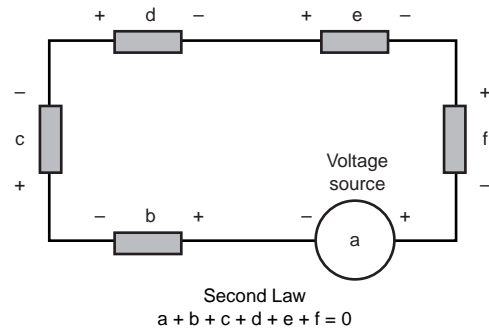

Kirchhoff's Laws for current and voltage

Also see **Ohm's Law**.

Kirchhoff's Laws for current and voltage are two principles that apply to DC circuits and networks.

The total **current** flowing into any DC circuit node, also called a branch point, is always the same as the total current flowing out of the node. An example is shown in the top illustration. There are four current-carrying conductors (**a**, **b**, **c**, and **d**) leading into the node (black dot), and two conductors (**e** and **f**) leading out. Direct currents in parallel add together arithmetically. Therefore, the total current flowing into the node is $a + b + c + d$, and the total current flowing out is $e + f$. These total currents, according to *Kirchhoff's First Law*, must be equal.

Kirchhoff's Second Law deals with **voltage**. An example is shown in the bottom illustration. A source having voltage equal to **a** is connected in a circuit with five passive components having voltage differences **b**, **c**, **d**, **e**, and **f** across them. The voltages across the passive components add together arithmetically because they are connected in series. According to the Second Law, the total voltage across the set of passive components is always equal and opposite to the source voltage. Therefore, the sum of the voltage differences across all the circuit elements (including the source) is always zero.

KISS Principle

The KISS (Keep It Simple, Stupid) Principle is self-descriptive and recognizes two things:

1. People (including product and service users) generally want things that are simple, meaning easy to learn and use.
2. A company that makes products or furnishes services may find simplicity an advantage for the company as well, since it tends to shorten time and reduce cost. (Where the company is trying to use the principle on behalf of users, however, design time may take longer and cost more, but the net effect will be beneficial since easy-to-learn-and-use products and services tend to be cheaper to produce and service in the long run.)

The New Hacker's Dictionary, edited by Eric Raymond, says the the KISS Principle is sometimes cited on a development project to fend off "creeping featurism."

The somewhat related idea of **Ockham's razor** is about always looking for the simplest explanation.

KLOC

KLOC (thousands of lines of code) is a traditional measure of how large a computer **program** is or how long or how many people it will take to write it. The code measured is usually **source code**. Since a higher-level source language (such as **C++**) **compiles** into more lines of **machine code** than a lower-level language (such as **assembler** language), a KLOC

of C++ statements would generate a larger program (in number of **bytes**) than a KLOC of assembler language statements.

KLOC has been used as a rough measure of programmer productivity, as in “How many lines of code can you write a day?” However, this measure does not consider the efficiency of the code. Many other factors obviously affect productivity.

Defects per KLOC is a common measure used as a target or for evaluating code quality.

kludge

In information technology, a kludge (pronounced KLOOdzh) is an awkward or clumsy (but at least temporarily effective) solution to a programming or hardware design or implementation problem. According to Eric Raymond, the term is indirectly derived from the German *klug* meaning clever. Raymond considers “kludge” an incorrect spelling of *kluge*, a term of the 1940s with the same general meaning and possibly inspired by the Kluge paper feeder, a “fiendishly complex assortment of cams, belts, and linkages...devilishly difficult to repair...but oh, so clever!”

A kludge originates because another, more elegant or appropriate solution is not currently possible (perhaps because of time constraints). Hardware and software products are sometimes the result of adding a new and basically incompatible design to the original design rather than redesigning the product completely. What is a kludge can be a matter of opinion. Users often have a different opinion than the designers, who understand the problems that had to be overcome. To the extent that information technology products are combinations of elements originating from a variety of design philosophies and constraints, almost any product is bound to contain some element of kludginess.

knowbot

A knowbot is a program that automatically searches Internet sites and gathers information from them according to user-specified criteria. A knowbot is more frequently called an **intelligent agent** or simply an **agent**. A knowbot should not be confused with a **search engine crawler** or **spider**. A crawler or spider program visits Web sites and gathers information according to some generalized criteria and this information is then indexed so that it can be used for searching by many individual users. A knowbot works with specific and easily changed criteria that conform to or anticipate the needs of the user or users. Its results are then organized for presentation but not necessarily for searching. An example would be a knowbot (sometimes also called a *newsbot*) that visited major news-oriented Web sites each morning and provided a digest of stories (or links to them) for a personalized news page.

knowledge

In information technology, knowledge is, to an enterprise or an individual, the possession of **information** or the ability to quickly locate it. This is essentially what Samuel Johnson, compiler of the first comprehensive English dictionary, said when he wrote that:

Knowledge is of two kinds: We know a subject ourselves, or we know where we can find information upon it.

In the context of the business enterprise or the personal computer user, knowledge tends to connote possession of experienced “know-how” as well as possession of factual information or where to get it. Enterprises have recently begun to treat their accumulated knowledge as an asset and to develop **knowledge management** plans and applications. A new kind of application, called **data mining**, attempts to develop knowledge from a company’s accumulated business transactions and other **data**.

In philosophy, the theory of knowledge is called *epistemology* and deals with such questions as how much knowledge comes from experience or from innate reasoning ability; whether knowledge needs to be believed or can simply be used; and how knowledge changes as new ideas about the same set of facts arise.

knowledge base

In general, a knowledge base is a centralized repository for information: A public library, a database of related information about a particular subject, and whatis.com could all be considered to be examples of knowledge bases. In relation to information technology (IT), a knowledge base is a machine-readable resource for the dissemination of information, generally **online** or with the capacity to be put online. An integral component of **knowledge management** systems, a knowledge base is used to optimize information collection, organization, and retrieval for an organization, or for the general public.

A well-organized knowledge base can save an **enterprise** money by decreasing the amount of employee time spent trying to find information about—among myriad possibilities—tax laws or company policies and procedures. As a customer relationship management (CRM) tool, a knowledge base can give customers easy access to information that would otherwise require contact with an organization’s staff; as a rule, this capacity should make the interaction simpler for both the customer and the organization. A number of software applications are available that allow users to create their own knowledge bases, either separately (these are usually called *knowledge management software*) or as part of another application, such as a CRM package.

In general, a knowledge base is not a static collection of information, but a dynamic resource that may itself have the capacity to learn, as part of an artificial intelligence (AI) **expert system**, for example. According to the World Wide Web Consortium (W3C), in the future the Internet may become a vast and complex global knowledge base. Tim Berners-Lee calls this the **Semantic Web**.

knowledge management

Knowledge management is the name of a concept in which an **enterprise** consciously and comprehensively gathers, organizes, shares, and analyzes its **knowledge** in terms of resources, documents, and people skills. In early 1998, it was believed that few enterprises actually had a comprehensive knowledge management practice (by any name) in operation. Advances in technology and the way we access and share information have changed that; many enterprises now have some kind of knowledge management framework in place.

Knowledge management involves **data mining** and some method of operation to **push** information to users. Some vendors are offering products to help an enterprise inventory and access knowledge resources. The Lotus Knowledge Discovery System, for example, advertises that it can locate and organize relevant content and expertise required to address specific business tasks and projects. It will analyze the relationships between content, people, topics, and activity, and produce a knowledge map report, based on a point system, that can be shared.

In an *Information Week* article, Jeff Angus and Jeetu Patel describe a four-process view of knowledge management that we have put into a table:

This major process...	Includes these activities....
Gathering	<ul style="list-style-type: none"> ● Data entry ● OCR and scanning ● Voice input ● Pulling information from various sources ● Searching for information to include
Organizing	<ul style="list-style-type: none"> ● Cataloging ● Indexing ● Filtering ● Linking
Refining	<ul style="list-style-type: none"> ● Contextualizing ● Collaborating ● Compacting ● Projecting ● Mining
Disseminating	<ul style="list-style-type: none"> ● Flow ● Sharing ● Alert ● Push

A knowledge management plan involves a survey of corporate goals and a close examination of the tools, both traditional and technical, that are required for addressing the needs of the company. The challenge is to select or build software that fits the context of the overall plan and encourage employees to share information.

knowledge worker

A knowledge worker is anyone who works for a living at the tasks of developing or using **knowledge**. For example, a knowledge worker might be someone who works at any of the tasks of planning, acquiring, searching, analyzing, organizing, storing, programming, distributing, marketing, or otherwise contributing to the transformation and commerce of information and those (often the same people) who work at using the knowledge so produced. A term first used by Peter Drucker in his 1959 book, *Landmarks of Tomorrow*, the knowledge worker includes those in the information technology fields, such as programmers, systems analysts, technical writers, academic professionals, researchers, and so forth. The term is also frequently used to include people outside of information technology, such as lawyers, teachers, scientists of all kinds, and also students of all kinds.

Korn shell

The Korn shell is the **UNIX shell** (command execution program, often called a *command interpreter*) that was developed by David Korn of Bell Labs as a comprehensive combined version of other major UNIX shells. Incorporating all the features of **C shell** (*csh*) and Tab C-shell (*tcsh*) with the script language features similar to that of the **Bourne shell**, the Korn shell is considered the most efficient shell. Korn, Bourne, and C are the three most commonly used UNIX shells.

The Korn shell is considered a member of the Bourne shell family and uses as its shell prompt (character displayed to indicate readiness for user input) the \$ symbol. Because it is the easiest shell to use, inexperienced users usually prefer the Korn shell and, not surprisingly, it is the one most often used in commercial environments.

Sometimes known by its program name *ksh*, the Korn is the default shell on many UNIX systems.

KVM switch

A KVM (keyboard, video, mouse) switch allows a single **keyboard**, video display **monitor**, and **mouse** to be switched to any of a number of computers when typically a single person interacts with all the computers but only one at a time. The switch provides more table space in addition to saving the cost of multiple keyboards and monitors. KVM switches are commonly used at Web and other **server** locations with multiple computers but usually a single administrator or Webmaster. The switches range in price

from about \$200 U.S. for a system in which up to eight computers can be daisy-chained to about \$2,000 for a switch that controls up to 10 Sun workstations. Larger configurations can cost more.

L

L1 and L2

L1 and L2 are levels of **cache memory** in a computer. If the computer processor can find the data it needs for its next operation in cache memory, it will save time compared to having to get it from **random access memory**. L1 is “level-1” cache memory, usually built onto the microprocessor chip itself. For example, the Intel **MMX** microprocessor comes with 32 thousand bytes of L1.

L2 (that is, level-2) cache memory is on a separate **chip** (possibly on an expansion **card**) that can be accessed more quickly than the larger “main” memory. A popular L2 cache memory size is 1,024 kilobytes (one megabyte).

L2TP

See “Layer Two Tunneling Protocol”

lambda

LAMBDA

Upper Case Λ

Lower Case λ

Lambda, the 11th letter of the Greek alphabet, is the symbol for **wavelength**. In **optical fiber** networking, the word lambda is used to refer to an individual optical wavelength.

lambda calculus

Lambda calculus, considered to be the mathematical basis for programming language, is a calculus developed by Alonzo Church and Stephen Kleene in the 1930s to express all computable functions. In an effort to formalize the concept of computability (also known as constructibility and effective calculability), Church and Kleene developed a powerful language with a simple **syntax** and few grammar restrictions. The language deals with the application of a **function** to its arguments (a function is a set of rules) and expresses any **entity** as either a variable, the application of one function to another, or as a “lambda abstraction” (a function in which the Greek letter lambda is defined as the abstraction operator). Lambda calculus, and the closely related theories of combinators and type systems, are important foundations in the study of mathematics, logic, and computer programming language.

lambda switching

Lambda switching (sometimes called *photonic* switching, or *wavelength* switching) is the technology used in optical networking to switch individual wavelengths of light onto separate paths for specific routing of information. In conjunction with technologies such as dense wavelength division multiplexing (**DWDM**)—which enables 80 or more separate light **wavelengths** to be transmitted on a single optical fiber—lambda switching enables a light path to behave like a **virtual circuit**.

Although the ability to redirect specific wavelengths intelligently is, in itself, a technological breakthrough, lambda switching works in much the same way as traditional routing and switching. Lambda **routers**—which are also called *wavelength* routers, or *optical cross-connects* (**OXC**)—are positioned at network junction points. The lambda router takes in a single wavelength of light from a specific **fiber optic** strand and recombines it into another strand that is set on a different path. Lambda routers are being manufactured by a number of companies, including Ciena, Lucent, and Nortel.

Multiprotocol Lambda Switching is a variation of multiprotocol label switching (**MPLS**, confusingly, the abbreviation for both variants) in which specific wavelengths serve in place of labels as unique identifiers. The specified wavelengths, like the labels, make it possible for routers and switches to perform necessary functions automatically, without having to extract instructions regarding those functions from **IP addresses** or other **packet** information.

Lambda switching gets its name from *lambda*, the 11th letter of the Greek alphabet, which has been adopted as the symbol for *wavelength*. In networking, the word is used to refer to an individual optical wavelength.

lamer

Lamer is a term used on interactive Web sites to describe an irritating or immature participant. Among users of Internet Relay Chat (**IRC**), a lamer is someone who irritates other users by typing in all caps or iN pART cAPS, by insulting and **flaming** other users, by typing abbreviations for almost every word, or by performing other annoying acts in chat rooms. Some IRC **channels** use **bots** to monitor any “lame” behavior and kick lamers out.

Lamer is also used by **crackers** and **warez** d00dz. Warez d00dz (that is, “wares dudes”) are people who strip software of its copyright protection and then distribute the pirated software on the Internet for downloading. Warez d00dz sometimes compete to distribute the pirated software before other warez d00dz groups. People who create warez sites sometimes call them “warez sitez” and use “z” in other

pluralizations. A lamer according to the warez d00dz culture is an individual who tries to distribute software that is several years old or software infected with a virus. Crackers use the term in a non-derogatory way to refer to cracker aspirants who are in the larval or beginning stage of computer cracking.

LAN

See “local area network”

LAN server

A local area network (LAN) server is a program (and by implication usually the computer it runs in) that serves resources (files, storage, application programs, printers, and other devices) to a number of attached workstations.

In an enterprise, a LAN server has an administrator (or someone who fills that role) and typically LAN services and the setting up and administration of the local area network are managed on behalf of users but not directly by the users.

A LAN server can also be housed in a computer that has other servers such as a **proxy server**.

LANDesk Client Manager

LDCM (LANDesk Client Manager) is a software product from Intel that lets a system administrator for a local area network (LAN) see the configurations and monitor the status of **personal computers** on the LAN. LDCM is an implementation of the Desktop Management Interface (DMI) standard established by the Desktop Management Task Force, an industry group. To take advantage of DMI, product components must provide a Management Information Format (MIF) file.

Using LDCM, a LAN administrator can be notified automatically when a workstation is nearing problem status. LDCM’s “PC health monitoring” can notify the administrator of the status of low **memory**, any recoverable **parity** error, any **boot virus** that may be present, the **motherboard** and **central processing unit** temperatures, and other status information. LDCM also allows an inventory to be kept of all software and hardware characteristics of all workstations.

The first releases of LDCM have been pre-installed on PCs by original equipment manufacturers. LDCM requires a **BIOS** that supports System Management BIOS Specification Version 2.0.

landing page

See “jump page”

Langmuir-Blodgett film

A Langmuir-Blodgett (LB) film is a set of monolayers, or layers of organic material one molecule thick, deposited on a solid substrate. An LB film can consist of a single layer or many, up to a depth of several visible-light **wavelengths**.

The term Langmuir-Blodgett comes from the names of a research scientist and his assistant, Irving Langmuir and Katherine Blodgett, who discovered unique properties of thin films in the early 1900s. Langmuir’s original work involved the transfer of monolayers from liquid to solid substrates. Several years later, Blodgett expanded on Langmuir’s research to include the deposition of multi-layer films on solid substrates.

By transferring monolayers of organic material from a liquid to a solid substrate, the structure of the film can be controlled at the molecular level. Such films exhibit various electrochemical and photochemical properties. This has led some researchers to pursue LB films as a possible structure for integrated circuits (ICs). Ultimately, it might be possible to construct an LB-film memory chip in which each data bit is represented by a single molecule. Complex switching networks might be fabricated onto multilayer LB-films chips.

laptop computer

This definition is very similar to our definition for **notebook computer**. Also see **portable computer**.

A laptop computer, usually called a *notebook computer* by manufacturers, is a battery-powered personal computer generally smaller than a briefcase that can easily be transported and conveniently used in temporary spaces such as on airplanes, in libraries, temporary offices, and at meetings. A laptop typically weighs less than 5 pounds and is 3 inches or less in thickness. Among the best-known makers of laptop computers are IBM, NEC, Dell, Toshiba, and Hewlett-Packard.

Laptop computers generally cost more than desktop computers with the same capabilities because they are more difficult to design and manufacture. A laptop can effectively be turned into a desktop computer with a **docking station**, a hardware frame that supplies connections for peripheral input/output devices such as a printer or larger monitor. The less capable *port replicator* allows you to connect a laptop to a number of peripherals through a single plug.

Laptops usually come with displays that use thin-screen technology. The **thin film transistor** or active matrix screen is brighter and views better at different angles than the STN or dual-scan screen. Laptops use several different approaches for integrating a **mouse** into the keyboard, including the **touch pad**, the **trackball**, and the pointing stick. A serial port also allows a regular mouse to be attached. The **PC Card** is insertable hardware for adding a **modem** or **NIC** to a laptop. CD-ROM and **digital versatile disk** drives may be built-in or attachable.

laser

The acronym *laser* stands for “light amplification by stimulated emission of radiation.” Lasers work as a result of resonant effects. The output of a laser is a coherent **electromagnetic field**. In a coherent beam of electromagnetic energy, all the waves have the same **frequency** and **phase**.

Coherent electromagnetic waves have identical frequency, and are aligned in phase.

In a basic laser, a chamber called a *cavity* is designed to internally reflect infrared (IR), visible-light, or ultraviolet (UV) waves so they reinforce each other. The cavity can contain gases, liquids, or solids. The choice of cavity material determines the wavelength of the output. At each end of the cavity, there is a mirror. One mirror is totally reflective, allowing none of the energy to pass through; the other mirror is partially reflective, allowing approximately 5 percent of the energy to pass through. Energy is introduced into the cavity from an external source; this is called *pumping*.

As a result of pumping, an electromagnetic field appears inside the laser cavity at the natural (resonant) frequency of the atoms of the material that fills the cavity. The waves reflect back and forth between the mirrors. The length of the cavity is such that the reflected and re-reflected wavefronts reinforce each other in phase at the natural frequency of the cavity substance. Electromagnetic waves at this resonant frequency emerge from the end of the cavity having the partially-reflective mirror. The output may appear as a continuous beam, or as a series of brief, intense pulses.

The *ruby laser*, a simple and common type, has a rod-shaped cavity made of a mixture of solid aluminum oxide and chromium. The output is in pulses that last approximately 500 microseconds each. Pumping is done by means of a helical flash tube wrapped around the rod. The output is in the red visible range.

A simple laser works via resonant effects in a cavity with mirrors at either end.

The *helium-neon laser* is another popular type, favored by electronics hobbyists because of its moderate cost. As its name implies, it has a cavity filled with helium and neon gases. The output of the device is bright crimson. Other gases can be used instead of helium and neon, producing beams of different wavelengths. Argon produces a laser with blue visible output. A mixture of nitrogen, carbon dioxide, and helium produces IR output.

Lasers are one of the most significant inventions developed during the 20th century. They have found a tremendous variety of uses in electronics, computer hardware, medicine, and experimental science.

laser diode

Also see **diode**.

A laser diode, also known as an *injection laser* or *diode laser*, is a **semiconductor** device that produces coherent radiation (in which the waves are all at the same frequency and phase) in the visible or **infrared** (IR) spectrum when **current** passes through it. Laser diodes are used in **optical fiber** systems, compact disc (CD) players, **laser printers**, remote-control devices, and **intrusion detection** systems.

Laser diodes differ from conventional lasers, such as the helium-neon (He-Ne), ruby, and gas types, in several ways.

- **Small size and weight:** A typical laser diode measures less than one millimeter across and weighs a fraction of a gram, making it ideal for use in portable electronic equipment.
- **Low current, voltage, and power requirements:** Most laser diodes require only a few milliwatts of power at 3 to 12 volts DC and several milliamperes. Therefore, they can operate using small battery power supplies.
- **Low intensity:** A laser diode cannot be used for spectacular purposes such as burning holes in metal, bringing down satellites, or blinding aircraft pilots. Nevertheless, its coherent output results in high efficiency and ease of **modulation** for communications and control applications.
- **Wide-angle beam:** A laser diode produces a “cone” rather than a “pencil” of visible light or IR, although this “cone” can be collimated using convex lenses.

laser printer

A laser printer is a popular type of personal computer **printer** that uses a non-impact (keys don't strike the paper), photocopier technology. When a document is sent to the printer, a laser beam "draws" the document on a selenium-coated drum using electrical charges. After the drum is charged, it is rolled in toner, a dry powder type of ink. The toner adheres to the charged image on the drum. The toner is transferred onto a piece of paper and fused to the paper with heat and pressure. After the document is printed, the electrical charge is removed from the drum and the excess toner is collected. Most laser printers print only in monochrome. A color laser printer is up to 10 times more expensive than a monochrome laser printer.

IBM introduced the first laser printer in 1975 for use with its **mainframe** computers. In 1984, Hewlett-Packard revolutionized laser-printing technology with its first LaserJet, a compact, fast, and reliable printer that personal computer users could afford. Since then, laser printers have decreased further in price and increased in quality. Hewlett Packard continues to be the leading manufacturer with competitors including Lexmark, Okidata, and Xerox.

The laser printer is different from an inkjet printer in a number of ways. The toner or ink in a laser printer is dry. In an inkjet, it is wet. Over time, an inkjet printer is about ten times more expensive to operate than a laser printer because ink needs replenishing more frequently. The printed paper from an inkjet printer will smear if wet, but a laser-printed document will not. Both types of printer operate quietly and allow fonts to be added by using **font** cartridges or installing soft fonts. If your printing needs are minimal, an inkjet printer is sufficient. But if your printing volume is high, consider buying a laser printer.

When buying a laser printer, these are some important features to consider:

Print capacity and speed: Personal laser printers are sufficient for printing an average of 200 pages per week. These are low-end and cost \$200 and up. They can print up to eight ppm (pages per minute). A workgroup printer is needed if an average of 1000 pages per week is needed. These print up to 24 ppm and cost \$1000 to \$6000 and more. Production printers are needed for printing 50,000 or more pages per week. These are quite expensive and are used by commercial publishers. They can print up to 700 ppm and cost \$100,000 and up. They can print 24 hours a day, seven days a week.

Resolution: The standard **resolution** in most laser printers today is 600 dots-per-inch (**dpi**). This resolution is sufficient for normal everyday printing including small desktop publishing jobs. A high-end production printer might have a resolution of 2400 dpi. Some laser printers still use a resolution of 300 dpi. This resolution can cause jagged lines to appear on the outer edge of an image. Hewlett Packard created RET (Resolution Enhancement Technology) to

correct this. RET inserts smaller dots at the edges of lines and to smooth the rough edges. RET does not improve the resolution, but the document looks better. If you purchase a printer with 300 dpi, make sure it has RET.

Printer languages: Printer Control Language (**PCL**) is the standard printer language for Hewlett Packard and most other laser printers (which are mostly HP-compatible). PCL is used for printing letters, database printouts, spreadsheets, and simple graphics. **Postscript** printers are used with desktop publishing software and drawing packages. Postscript printers are the norm for Apple **Macintosh** printers. A laser printer that comes with Postscript installed is more expensive. A laser printer that uses PCL can be upgraded to Postscript by installing a software driver provided by the manufacturer of the laser printer. The printer might require more **memory** when upgraded to use Postscript. This is because a laser printer needs the entire image in memory before printing, and a Postscript printer requires more memory to process than a PCL printer does. The application being used must support Postscript in order for the laser printer to print Postscript documents.

Paper handling: Paper handling is important when shopping for a laser printer. Most laser printers use letter-size, cut-sheet paper. High-end production printers use continuous sheet paper. Laser printers can print on transparencies, adhesive labels, and lightweight cards. A laser printer with duplex printing can print on one side of the paper, turn the paper over, and print on the other side. Most laser printers, however, use simple printing with manual duplex printing. Manual duplex printing is achieved by changing the print options in the printer's properties or printing one side and taking that same paper and reinserting it into the printer to print on the other side.

FPOT and warm-up time: A final consideration in purchasing a printer is FPOT (first paper out time) and warm-up time. When a laser printer receives data from the computer to print, it takes 5 to 30 seconds to prepare the printer to print a new job. This is in addition to the time it takes to actually print the document. The warm-up time is as important. When the printer is turned on, it needs time to warm up the fuser to operating temperature. If the printer has a standby mode or is turned off between printing jobs, the warm-up time becomes even more important. Large workgroup and production printers can take 5 to 15 minutes to warm up. This waiting period can hinder overall productivity.

laserdisc

Laserdisc is a technology and the physical medium used in storing and providing programmed access to a large database of text, pictures, and other objects, including motion video and full multimedia presentations.

The laserdisc itself is 12 inches in diameter and holds much more information than a CD-ROM disc can currently hold. Laserdiscs require relatively expensive players and are more

expensive to distribute than CD-ROM discs. However, for school and corporate education purposes and any presentation requiring a great deal of motion video and the ability to create scripted or programmed access to selected portions of the laserdisc, the technology can be useful.

last-mile technology

Last-mile technology is any telecommunications technology, such as **wireless** radio, that carries **signals** from the broad telecommunication along the relatively short distance (hence, the “last mile”) to and from the home or business. Or to put it another way: the infrastructure at the neighborhood level. In many communities, last-mile technology represents a major remaining challenge to high-bandwidth applications such as on-demand television, fast Internet access, and Web pages full of multimedia effects.

Today, in addition to “plain old telephone (dial-up) service,” last-mile technologies to deliver voice, data, and TV can include:

- **ISDN**, a somewhat faster technology than regular phone service
- Digital Subscriber Line (**DSL**) over existing telephone **twisted pair** lines
- Cable and the **cable modem** for data, using the same installed **coaxial cable** that already is used for television
- **Wireless**, including services such as DirecTV
- Less frequently because of the installation expense, **optical fiber** and its transmission technologies

LATA

See “local access and transport area”

latency

1) In a network, latency, a synonym for *delay*, is an expression of how much time it takes for a **packet** of data to get from one designated point to another. In some usages (for example, AT&T), latency is measured by sending a packet that is returned to the sender and the round-trip time is considered the latency.

The latency assumption seems to be that data should be transmitted instantly between one point and another (that is, with no delay at all). The contributors to network latency include:

- **Propagation:** This is simply the time it takes for a packet to travel between one place and another at the speed of light.
- **Transmission:** The medium itself (whether **optical fiber**, **wireless**, or some other) introduces some delay. The size of the packet introduces delay in a round trip since a larger packet will take longer to receive and return than a short one.

- **Router and other processing:** Each **gateway node** takes time to examine and possibly change the header in a packet (for example, changing the **hop** count in the **time-to-live** field).
- **Other computer and storage delays:** Within networks at each end of the journey, a packet may be subject to storage and hard disk access delays at intermediate devices such as **switches** and **bridges**. (In backbone statistics, however, this kind of latency is probably not considered.)

2) In a computer system, latency is often used to mean any delay or waiting that increases real or perceived **response time** beyond the response time desired. Specific contributors to computer latency include mismatches in data speed between the **microprocessor** and input/output devices and inadequate data **buffers**.

Within a computer, latency can be removed or “hidden” by such techniques as *prefetching* (anticipating the need for data input requests) and *multithreading*, or using parallelism across multiple execution threads.

3) In 3D simulation, in describing a helmet that provides stereoscopic vision and head tracking, latency is the time between the computer detecting head motion to the time it displays the appropriate image.

layer

See “layering”

layer 2

Layer 2 refers to the Data Link **layer** of the commonly-referenced multilayered communication model, Open Systems Interconnection (**OSI**). The Data Link layer is concerned with moving data across the physical links in the network. In a network, the **switch** is a device that redirects data messages at the layer 2 level, using the destination Media Access Control (**MAC**) address to determine where to direct the message.

The Data-Link layer contains two sublayers that are described in the IEEE-802 LAN standards:

- **Media Access Control** (**MAC**) sublayer
- **Logical Link Control** (**LLC**) sublayer

The Data Link layer ensures that an initial connection has been set up, divides output data into data frames, and handles the acknowledgements from a receiver that the data arrived successfully. It also ensures that incoming data has been received successfully by analyzing bit patterns at special places in the frames.

layer 3

Layer 3 refers to the **Network layer** of the commonly referenced multilayered communication model, Open Systems Interconnection (**OSI**). The Network layer is

concerned with knowing the address of the neighboring nodes in the network, selecting routes and quality of service, and recognizing and forwarding to the **Transport layer** incoming messages for local host domains.

A **router** is a layer 3 device, although some newer **switches** also perform layer 3 functions. The Internet Protocol (**IP**) address is a layer 3 address.

Layer Two Tunneling Protocol

Layer Two Tunneling Protocol (L2TP) is an extension of the Point-to-Point Tunneling Protocol (**PPTP**) used by an Internet service provider (**ISP**) to enable the operation of a virtual private network (**VPN**) over the Internet. L2TP merges the best features of two other tunneling protocols: PPTP from Microsoft and L2F from Cisco Systems. The two main components that make up L2TP are the L2TP Access Concentrator (**LAC**), which is the device that physically terminates a call and the L2TP Network Server (**LNS**), which is the device that terminates and possibly authenticates the PPP stream.

PPP defines a means of encapsulation to transmit multiprotocol packets over layer two (L2) point-to-point links. Generally, a user connects to a network access server (**NAS**) through ISDN, ADSL, dialup POTS or other service and runs PPP over that connection. In this configuration, the L2 and PPP session endpoints are both on the same NAS.

L2TP uses packet-switched network connections to make it possible for the endpoints to be located on different machines. The user has an L2 connection to an access concentrator, which then tunnels individual PPP frames to the NAS, so that the packets can be processed separately from the location of the circuit termination. This means that the connection can terminate at a local circuit concentrator, eliminating possible long-distance charges, among other benefits. From the user's point of view, there is no difference in the operation.

layering

In computer programming, layering is the organization of programming into separate functional components that interact in some sequential and hierarchical way, with each layer usually having an interface only to the layer above it and the layer below it.

Communication programs are often layered. The reference model for communication programs, Open System Interconnection (**OSI**) is a layered set of protocols in which two multilayered programs, one at either end of a communications exchange, use an identical set of layers. In the OSI model, each multilayer program contains seven layers, each reflecting a different function that has to be performed in order for program-to-program communication to take place between computers.

TCP/IP is an example of a two-layer (**TCP** and **IP**) set of programs that provide transport and network address functions for Internet communication. A set of TCP/IP and other layered programs is sometimes referred to as a **protocol stack**.

LCD

LCD (liquid crystal display) is the technology used for displays in notebook and other smaller computers. Like light-emitting diode (**LED**) and gas-plasma technologies, LCDs allow displays to be much thinner than cathode ray tube (**CRT**) technology. LCDs consume much less power than LED and gas-display displays because they work on the principle of blocking light rather than emitting it.

An LCD is made with either a passive matrix or an **active matrix** display grid. The active matrix LCD is also known as a thin film transistor (**TFT**) display. The passive matrix LCD has a grid of conductors with pixels located at each intersection in the grid. A current is sent across two conductors on the grid to control the light for any **pixel**. An active matrix has a **transistor** located at each pixel intersection, requiring less current to control the luminance of a pixel. For this reason, the current in an active matrix display can be switched on and off more frequently, improving the screen refresh time (your mouse will appear to move more smoothly across the screen, for example).

Some passive matrix LCD's have dual scanning, meaning that they scan the grid twice with current in the same time that it took for one scan in the original technology. However, active matrix is still a superior technology.

LDIF

LDIF (Lightweight Directory Interchange Format) is an **ASCII file format** used to exchange data and enable the synchronization of that data between Lightweight Directory Access Protocol (**LDAP**) **servers** called Directory System Agents (DSAs). LDAP is a software **protocol** for enabling anyone to locate organizations, individuals, and other resources such as files and devices in a network. An LDAP directory can be distributed among many servers. LDIF is used to synchronize each LDAP directory.

The first step in synchronizing LDAP directories is extracting the full contents of or a portion of the original LDAP directory and formatting the contents into an LDIF file. The LDIF file is then mailed to a directory synchronization robot called DIRBOT. After several different steps, a final LDIF file is compared to the original LDIF file. The update instructions on what records to add, delete, or modify in the original directory are decided. These updates are then used to synchronize all LDAP directories.

leased line

A leased line is a telephone line that has been leased for private use. In some contexts, it's called a *dedicated* line. A leased line is usually contrasted with a *switched line* or *dial-up line*.

Typically, large companies rent leased lines from the telephone message carriers (such as AT&T) to interconnect different geographic locations in their company. The alternative is to buy and maintain their own private lines or, increasingly perhaps, to use the public switched lines with secure message protocols. (This is called **tunneling**.)

LEC

LEC (local exchange carrier) is the term for a public telephone company in the U.S. that provides local service. Some of the largest LECs are the Bell operating companies (**BOCs**) which were grouped into holding companies known collectively as the regional Bell operating companies (**RBOCs**) when the Bell System was broken up by a 1983 consent decree. In addition to the Bell companies, there are a number of independent LECs, such as GTE.

LEC companies are also sometimes referred to as "telcos." A "local exchange" is the local "central office" of an LEC. Lines from homes and businesses terminate at a local exchange. Local exchanges connect to other local exchanges within a local access and transport area (**LATA**) or to interexchange carriers (**IXCs**) such as long-distance carriers ATT, MCI, and Sprint.

legacy application

In information technology, legacy applications and data are those that have been inherited from languages, platforms, and techniques earlier than current technology. Most **enterprises** who use computers have legacy applications and databases that serve critical business needs. Typically, the challenge is to keep the legacy application running while converting it to newer, more efficient code that makes use of new technology and programmer skills. In the past, much programming has been written for specific manufacturers' operating systems. Currently, many companies are migrating their legacy applications to new programming languages and operating systems that follow **open** or standard programming interfaces. Theoretically, this will make it easier in the future to update applications without having to rewrite them entirely and will allow a company to use its applications on any manufacturer's operating system.

In addition to moving to new languages, enterprises are redistributing the locations of applications and data. In general, legacy applications have to continue to run on the platforms they were developed for. Typically, new development environments account for the need to continue to support legacy applications and data. With many new tools, legacy databases can be accessed by newer programs.

leverage

In the physical sense, leverage is an assisted advantage. As a verb, to *leverage* means to gain an advantage through the use of a tool. For example, you can more easily lift a heavy object with a lever than you can lift it unaided. Leverage is commonly used in a metaphorical sense. For example, as a frequently used business or marketing term, leverage is any strategic or tactical advantage, and as a verb, means to exploit such an advantage, just as the use of a physical lever gives one an advantage in the physical sense.

Leverage is a very popular business term on the Web. **B2B** Web sites offer to leverage Web sites, code, interactivity, storage area networks, database technology, and many other things. In the world of finance, leverage is the use of borrowed money to make an investment and the return on an investment.

LexiBot

LexiBot is a specialized search tool developed by BrightPlanet, as a means of searching the **deep Web** (the hidden part of the Web that may contain 500 times the

content accessible to conventional search engines). LexiBot uses what BrightPlanet calls a comprehensive and intelligent search technology that enables users to conduct searches using simple text, natural language, or **Boolean** queries on hundreds of databases simultaneously, filter and analyze data, and publish the results as Web pages. LexiBot was designed to perform complex searches to identify and retrieve content from all areas of the Web, and to process the information.
